the inhibition of mTORC1, can also regulate mTORC2 functioning. Indeed, the TSC1–TSC2 complex interacts with mTORC2, leading to its activation (Huang *et al.*, 2008).

Direct association between mTORC2 and ribosomes can activate mTORC2, and this event is regulated by PI3K activity (Zinzalla *et al.*, 2011). This mechanism suggests a possible link between both mTOR complexes in which mTORC2 promotes mTORC1 activity through the PI3K/Akt pathway and, in return, mTORC1 controls mTORC2 activity through the regulation of ribosomal biogenesis.

The PI3K/Akt/mTOR signaling cascade also cross talks with the p53 pathway. Indeed, p53 can regulate both TSC2 and AMPK (Feng *et al.*, 2007). Furthermore, AMPK may phosphorylate p53 at Ser 15, which leads to stabilization of p53 (Jones *et al.*, 2005). Hence, p53 and AMPK positively regulate each other. Moreover, phosphatase and tensin homolog (PTEN) may interact with p53, leading to its stabilization (Freeman *et al.*, 2003). As mentioned above, Akt is a negative regulator of p53 through MDM2. These cross regulations of AMPK, PTEN, and p53 oppose Akt activity and constitute a network coordinating cell division and growth after sensing nutrient availability, DNA integrity, and oncogenic activity.

Negative Regulation of PI3K/Akt/mTOR Pathway

The activity of several phosphatases counterbalances PI3K/Akt/mTOR activation, thus switching off this signaling cascade (Figure 3).

PI3Ks inactivation

The main phosphatases that can block the PI3K activity are PTEN, Src-homology 2 (SH2)-containing inositol 50-phosphatase (SHIP), and inositol polyphosphate 4-phosphatase type II (INPP4B), which hydrolyzes the 4-position of PtdIns(3,4)P₂.

PTEN is a ubiquitous phosphatase that can dephosphorylate the 3-position of PtdIns(3,4,5)P₃ to yield PtdIns(4,5)P₂ (Maehama and Dixon, 1998). Loss of PTEN activity due to inactivating mutations, deletions, or silencing has been reported in a wide range of both familial and sporadic human cancers (Sansal and Sellers, 2004).

The family of SHIP phosphatases includes two members, SHIP-1 and SHIP-2. These phosphatases dephosphorylate the 5-position of the inositol ring of PtdIns(3,4,5)P₃ to yield PtdIns3,4P₂ (Kalesnikoff *et al.*, 2003). While the SHIP-1 isoform is expressed in endothelial cells and in the hematopoietic lineage, SHIP-2 is ubiquitously expressed.

Akt inactivation

Akt function is also inactivated through the action of different phosphatases.

The phosphorylated Thr residues of Akt are dephosphorylated directly by protein phosphatase 2A (PP2A) (Ruvolo *et al.*, 2011). The core enzyme of PP2A is a dimer consisting of a catalytic subunit (PP2A/C α or β) and a regulatory/structural A subunit (PP2A/A α or β). A third regulatory B subunit (PP2A/B), which determines substrate specificity, can be associated with this core structure (Eichhorn *et al.*, 2009).

The phosphorylated Ser residues of Akt are targeted by the PH domain leucine-rich repeat protein phosphatase (PHLPP) family of isozymes. Three PHLPP isoforms have been identified so far: the alternatively spliced PHLPP1 α and PHLPP1 β , which target Akt2 and Akt3, and PHLPP2, which dephosphorylates Akt1 and Akt3 (Brognard *et al.*, 2007).

PI3K/Akt/mTOR Signaling in Human Disorders

Considering the crucial functions played by the PI3K/Akt/mTOR signaling pathway in several physiological processes, it appears evident that dysregulation of this axis could have dramatic consequences. Indeed, alterations in the PI3K/Akt/mTOR pathway are found in neurodegenerative diseases, cardiac hypertrophy, and metabolic disorders. Moreover, aberrantly activated PI3K/Akt/mTOR cascades are commonly observed in an increasing number of both solid tumors and hematological malignancies (Beauchamp and Platanias, 2013).

Regarding neurodegenerative diseases, it has been demonstrated that this pathway is involved in neuroprotection (Timmons *et al.*, 2009), enhancing cell survival via stimulation of cell proliferation and inhibition of apoptosis and autophagy (Heras-Sandoval *et al.*, 2014).

Recent evidence suggests that defective PI3K/Akt/mTOR signaling is associated with loss of dopaminergic neurons in Parkinson's disease (PD); in addition, a significant decrease in phospho-Akt at the Ser 473 residue has been reported in tyrosine hydroxylase TH immunoreactive dopaminergic neurons in the brains of PD patients (Timmons *et al.*, 2009).

Furthermore, this pathway appears to promote hyperphosphorylation of Tau, the main cause of formation of senile plaques and neurofibrillary tangles that characterize Alzheimer's disease (AD). In particular, GSK3 β , a downstream target of Akt, is probably the most documented kinase implicated in the abnormal hyper-phosphorylation of Tau protein (Hoover *et al.*, 2010). Moreover, alterations in the PI3K/Akt/mTOR pathway are linked to disruption of autophagy, and this event seems to be involved in the pathogenesis of AD and PD. Indeed, in both AD and PD, deficient elimination of abnormal and toxic protein aggregates promotes cellular stress and cell death. Therefore, induction of autophagy has been proposed as a reasonable strategy to help neurons in clearing abnormal protein aggregates and then to survive (Heras-Sandoval *et al.*, 2014).

Given the fundamental role of mTORC1 in the regulation of the autophagic process, beneficial outcomes can be achieved by modulating the PI3K/Akt/mTOR pathway: on the one hand, the induction of the above-mentioned cascade promotes survival and stops excessive autophagy that leads to cellular death; on the other hand, the inhibition of mTORC1 may stimulate autophagy of damaged or toxic proteins and then up-regulate cellular survival through mTORC2 activity on Akt.

Akt may also play a role in Huntington's disease (HD), as it phosphorylates huntingtin at Ser 421. Huntingtin phosphorylation is reduced at Ser 421 in HD patients (Warby *et al.*, 2005).

Another pathological condition linked to dysregulation of the PI3K/Akt/mTOR signaling axis is cardiac hypertrophy, one

of the main risk factors for heart failure. Cardiac hypertrophy is induced by increased cardiomyocyte volume, which is characterized by increased transcription and translation, as well as reduced protein turnover. The PI3K/Akt/mTOR pathway has been shown to directly regulate cardiomyocyte size, survival, angiogenesis, and inflammation in both physiological and pathological cardiac hypertrophy, through translational regulation by mTOR. Indeed, inhibition of mTORC1 by rapamycin treatment attenuated the hypertrophic response to pressure overload (McMullen *et al.*, 2004).

Insulin activates the PI3K/Akt signaling pathway in cardiomyocytes and substantially preserves and even improves regional and overall cardiac function. Insulin can protect cardiomyocytes from apoptosis by regulating a number of PI3K/Akt downstream signaling molecules, such as endothelial nitric oxide synthase (eNOS), GSK3 β , and mTORC1 (Yao and Han, 2014).

Type 2 diabetes is characterized by diminished pancreatic β -cell function, including decreased insulin secretion, as well as by peripheral insulin resistance in insulin-targeted tissues and organs. Insulin action elicits a series of signaling cascades initiated by insulin binding to its receptor, which causes receptor auto-phosphorylation and up-regulation of its RTK activity, resulting in tyrosine phosphorylation of IRSs. Phosphorylation of IRSs leads to activation of PI3K and, subsequently, of Akt and its downstream mediator, AS160, all of which are important steps in stimulating glucose transport induced by insulin. Studies on the skeletal muscle of type 2 diabetic patients have disclosed impaired insulin activation of the IRS1/PI3K/Akt signaling axis (Schultze *et al.*, 2012).

The involvement of PI3K/Akt/mTOR in tumorigenesis of multiple cancer types is well established (Katso *et al.*, 2001).

Dysregulation of the PI3K/Akt/mTOR pathway is more frequent than with any other pathway in human cancer (30–50% of all tumor types), with the possible exception of the p53 and retinoblastoma (Rb) pathways.

Moreover, PI3K/Akt/mTOR aberrant activity is not only found in many types of sporadic tumors but is also associated with familial cancer syndromes, such as Cowden's syndrome (CS), Peutz–Jegher's syndrome, tuberous sclerosis, and neurofibromatosis type-1 and type-2 (Carnero, 2010).

Pathologic activation of the PI3K/Akt/mTOR axis, leading to cancer onset, can occur at multiple levels and by various mechanisms, including PI3K/Akt point mutations, Akt amplification, and deletion/inactivation of tumor suppressor genes, including PTEN (Hennessy *et al.*, 2005).

Point mutations in PIK3CA, the gene encoding for the p110 α subunit of PI3K, are among the most commonly documented mutations in cancer (Samuels *et al.*, 2004). Indeed, these mutations have been described in nearly every major tumor type, including breast cancer, ovarian cancer, head and neck cancer, bowel cancer, gastric cancer, lung cancer, anaplastic oligodendrogliomas, anaplastic astrocytomas, glioblastoma multiforme, and medulloblastoma.

Mutations in PTEN have been identified in sporadic cancer; in particular, they have been found in endometrial, central nervous system, skin, and prostate cancers (Tamguney and Stokoe, 2007).

While somatic mutations are more common, germline loss of PTEN results in CS. CS is characterized by macrocephaly,

trichilemmomas, and papillomatous papules, as well as by a high risk of developing both benign and malignant tumors, especially of the thyroid, breast, and endometrium. CS is caused by PTEN monoallelic mutations that are sufficient to deregulate the PI3K/Akt/mTOR pathway, thus triggering carcinogenesis (Eng, 2003).

Furthermore, loss of PTEN activity could be due to deletions, transcriptional silencing, or protein instability due to posttranslational modification (Ali *et al.*, 1999).

In addition to inherent aberrations in members of the PI3K/Akt/mTOR pathway, pathologic signaling through this pathway can also occur by other means, including deregulation of RTKs, GPCRs, and oncogene, such as RAS (Chappell *et al.*, 2011).

Activation of the PI3K/Akt/mTOR pathway contributes to competitive growth advantage of cancer cells, metastatic competence, tumor angiogenesis, and, frequently, therapy resistance.

For all these reasons, PI3K/Akt/mTOR signaling is considered a valuable target for the development of innovative therapeutic strategies in cancer, and many small molecular inhibitors of this pathway are currently being tested in clinical trials.

Nevertheless, modulation of this signaling pathway could be beneficial to patients suffering from a wide variety of disorders other than cancer.

Highlights

- The PI3K/Akt/mTOR pathway plays a key role in many cellular processes, such as cell cycle progression, cellular survival, metabolism, and apoptosis.
- The PI3K/Akt/mTOR axis is extremely complex and tightly regulated.
- Dysregulation of PI3K/Akt/mTOR axis activity is associated with a wide range of pathological conditions.
- Targeting the PI3K/Akt/mTOR signaling cascade is considered a valuable and innovative therapeutic strategy for several disorders, including cancer.

The JAK–STAT–SOCS Signaling Cascade

JM Murphy, JJ Babon, NA Nicola, and SE Nicholson, Walter and Eliza Hall Institute of Medical Research, Melbourne, VIC, Australia and The University of Melbourne, Melbourne, VIC, Australia

© 2016 Elsevier Inc. All rights reserved.

Introduction

The JAK–STAT–SOCS signaling cascade is pivotal to the intracellular signal transduction initiated by many cytokine and growth factor receptors and as such drives numerous biological processes including hematopoiesis, innate and adaptive immunity, and growth and cellular differentiation. It has been the subject of intense research over the past 20 years and our understanding has grown exponentially. In essence, ligand binding to cognate cell surface receptors results in activation of the Janus kinases (JAK), which are constitutively associated with the receptor cytoplasmic domains. The JAKs, in turn, phosphorylate tyrosine residues within the receptor cytoplasmic domains to recruit signaling intermediates, such as the latent signal transducer and activator of transcription (STAT) proteins, which themselves become phosphorylated and move to the nucleus inducing a wave of gene transcription. The suppressors of cytokine signaling (SOCS) proteins act as a brake to limit the extent of JAK-mediated signaling, and are often induced as part of the STAT transcriptional response in a classic negative feedback loop.

The STATs were originally identified as components of an interferon (IFN)-regulated transcription complex (Levy *et al.*, 1988, 1989; Schindler *et al.*, 1992). Shortly thereafter, JAK1 and JAK2 were discovered in a degenerate polymerase chain reaction (PCR) screen (Wilks *et al.*, 1989; Wilks, 1991; Harpur *et al.*, 1992), whilst Tyk2 and JAK3 were independently discovered (Firmbach-Kraft *et al.*, 1990; Witthuhn *et al.*, 1993, 1994; Rane and Reddy, 1994; Takahashi and Shirasawa, 1994). The JAK family initially suffered from the misnomer of being ‘Just Another Kinase.’ However, it soon became clear that this unique family of protein tyrosine kinases were critical for the initiation of cytokine signaling (Johnston *et al.*, 1994; Witthuhn *et al.*, 1993, 1994) and they were renamed ‘Janus kinase’ for the two-headed Roman god of gates and in appreciation of the twin kinase domains (JH1 and JH2; see below). The positioning of the JAK and STAT proteins in the IFN cytokine cascades was delineated by an elegant series of somatic cell complementation studies performed in the Kerr and Stark laboratories in the early 1990s (Darnell *et al.*, 1994; Watling *et al.*, 1993; Shuai *et al.*, 1993; Velazquez *et al.*, 1992; Muller *et al.*, 1993). Whilst the full complement of mammalian STAT proteins (seven in total) were discovered in a burst of activity from 1992 to 1995 (Schindler *et al.*, 1992; Wakao *et al.*, 1994; Mui *et al.*, 1995; Liu *et al.*, 1995; Hou *et al.*, 1994; Zhong *et al.*, 1994; Akira *et al.*, 1994; Yamamoto *et al.*, 1994).

The field burgeoned and the analysis of genetically modified mice (Table 1) and the identification of various human mutations (Russell *et al.*, 1995; Macchi *et al.*, 1995) revealed the complex and highly specific nature of JAK–STAT recruitment by various receptor complexes.

Excessive cytokine signaling causes severe pathology in many inflammatory, allergic, and autoimmune disease states.

The SOCS proteins are small intracellular proteins that have a key role in controlling the immune response. SOCS1 was simultaneously discovered by three groups; in a screen for negative regulators of IL-6 signaling (Starr *et al.*, 1997) as a JAK-binding protein (Endo *et al.*, 1997) and based on antigenic similarity to the STAT3-SH2 domain (Naka *et al.*, 1997). Cytokine inducible SH2-containing protein (CIS) had been identified 2 years earlier and as its name suggests was identified as an interleukin (IL)-2, IL-3, granulocyte macrophage-colony stimulating factor (GM-CSF), and erythropoietin (EPO)-inducible protein (Yoshimura *et al.*, 1995). SOCS1 sequence similarity to CIS and database mining subsequently revealed a family of eight related mammalian SOCS proteins (Hilton *et al.*, 1998) that primarily function as adaptors to recruit an E3 ubiquitin ligase complex and regulate cytokine signaling.

A number of insights have been gained from the analysis of JAK–STAT signaling in *Drosophila*, which has an evolutionarily conserved but less redundant complement of JAKs, STATs, and SOCS. These are: Unpaired (ligand), Domeless (receptor), Hopscotch (JAK1/JAK2 homolog), STAT92E (STAT3/5 homolog), SOCS16D, SOCS44A (SOCS6/7 homolog), and SOCS36E (SOCS5 homolog) and are reviewed in Stec and Zeidler (2011). As an example, mutations in the pseudokinase domain of Hopscotch cause a leukemia-like disease (Luo *et al.*, 1995), not unlike the myeloproliferative disorders that result from mutation of valine 617 in the pseudokinase domain of human JAK2 (Cazzola and Kralovics, 2014).

It is important to acknowledge that in addition to the STATs, other pathways are activated following JAK activation and receptor phosphorylation (for instance, PI3K, PLC- γ , Ras-MAPK); similarly there are other ‘non-SOCS’ mechanisms for negative regulation of these pathways. The following summarizes our current understanding of the JAK–STAT–SOCS signaling cascade.

The JAK Family

The Evolution of the JAK Family

Cytokine receptor signal transduction relies on the association of the receptor intracellular portions with members of the JAK family of non-receptor tyrosine kinases. Cytokine receptors possess no intrinsic catalytic activity and as a result rely on recruitment of effector kinases, principally the JAKs, to convey signals. In vertebrates, there are four JAK family members, JAK1, JAK2, JAK3, and TYK2, each with common domain architecture (Figure 1(d)). The JAKs are composed of seven JAK-homology (JH) domains: at the N-terminus, JH7-4 constitute a FERM domain; JH3, an atypical SH2 domain; JH2, a pseudokinase domain; and at the C-terminus, JH1, the tyrosine kinase domain (Harpur *et al.*, 1992; Wilks *et al.*, 1991).

Table 1 The *in vivo* phenotypes caused by JAK/STAT/SOCS deficiency

Gene	Model	Viability	Phenotype	Cytokine signaling	References
Jak1	Mouse	Postnatal day 1 lethality	Death attributed to neurological defects from defective gp130 signaling. Small thymic and defective thymocyte production	IL-3; IL-2, IL-4, IL-7; IL-6, LIF; IFN α ; IFN γ ; IL-10; GM-CSF; IL-5; G-CSF	Rodrig <i>et al.</i> , 1998
Jak2	Mouse	Embryonic lethality at E12.5	Failure of definitive erythropoiesis	IL-3, IL-5, GM-CSF; IFN γ ; EPO; TPO; GH; prolactin (PRL); IL-6, LIF; IFN α / β ; G-CSF	Neubauer <i>et al.</i> , 1998; Parganas <i>et al.</i> , 1998; Wagner <i>et al.</i> , 2004
Jak2	Mouse	Lethal	PN4 lethality due to defective erythropoiesis. Adult mice succumbed to severe anemia, thrombocytopenia, stem cell loss, and bone marrow failure		Park <i>et al.</i> , 2013; Akada <i>et al.</i> , 2014; Grisouard <i>et al.</i> , 2014; Kremler <i>et al.</i> , 2004
		Viable	Impaired mammary gland development and maintenance of functionally differentiated alveolar cells		Wagner <i>et al.</i> , 2004
Jak3	Mouse	Viable	Develop severe combined immunodeficiency syndrome (SCID). Block in B-cell maturation in the bone marrow; smaller thymic and spleen size; and defective T cell function	IL-2, IL-4, IL-7, IL-9, IL-13, IL-15, IL-21	Nosaka <i>et al.</i> , 1995; Thomis <i>et al.</i> , 1995; Park <i>et al.</i> , 1995
JAK3	Human	Viable	Diminished T and NK cell numbers; normal B cell numbers		Macchi <i>et al.</i> , 1995; Russell <i>et al.</i> , 1995
Tyk2	Mouse	Viable	Macrophages unresponsive to lipopolysaccharide (LPS) stimulation. Reduced IL-12 mediated T-cell response following viral challenge	IL-12; IFN α / β and IFN γ (at low doses); IL-23; IL-3; IL-6, LIF; IL-10; G-CSF, TPO	Shimoda <i>et al.</i> , 2000; Karaghiosoff <i>et al.</i> , 2000, 2003; Shaw <i>et al.</i> , 2003; Ishizaki <i>et al.</i> , 2014
Tyk2	Mouse	Viable	Myeloid deletion reduced murine cytomegalovirus (MCMV) defense. Ubiquitous, but not lineage specific deletions, impaired tumor immunosurveillance		Vielhascher <i>et al.</i> , 2014
TYK2	Human	Viable	Susceptibility to viral, fungal, and mycobacteria infection. Atopic dermatitis		Minegishi <i>et al.</i> , 2006
STAT1	Mouse	Viable	Susceptibility to bacterial and viral infection	Type I IFN; IFN γ	Durbin <i>et al.</i> , 1996; Meraz <i>et al.</i> , 1996
STAT2	Mouse	Viable	Susceptibility to viral infection	Type I IFN	Park <i>et al.</i> , 2000

Table 1 Continued

Gene	Model	Model	Viability	Phenotype	Cytokine signaling	References
STAT3	Mouse	Germline knockout	Embryonic lethality at E6.5-7.5	Failure to form visceral endoderm	gp130 family cytokines; IL-10; G-CSF; leptin; IL-21, IL-23	Takeda <i>et al.</i> , 1997
		Conditional: Lung, bone, colon, heart, nervous system, and skin	Viable			Hokuto <i>et al.</i> , 2004; Zhang <i>et al.</i> , 2005; Welte <i>et al.</i> , 2003; Hliffiker-Kleiner <i>et al.</i> , 2004; Jacoby <i>et al.</i> , 2003; Okada <i>et al.</i> , 2006; Sano <i>et al.</i> , 1999
		'Knock-in' leptin receptor STAT3 mutant	Viable	Obesity		Bates <i>et al.</i> , 2003
STAT4	Mouse	Germline knockout	Viable	Reduced Th1 differentiation and natural killer cell function	IL-12; IL-23	Kaplan <i>et al.</i> , 1996; Thierfelder <i>et al.</i> , 1996
STAT5a	Mouse	Germline knockout	Viable	Defect in mammary gland development, failure to lactate	IL-3; GM-CSF; Prolactin; growth hormone; EPO; γ_c cytokines	Liu <i>et al.</i> , 1997
STAT5b STAT5a/b	Mouse Mouse	Germline knockout Compound germline knockout	Viable > 99% perinatal lethality	Impaired growth Severe anemia		Udy <i>et al.</i> , 1997 Socolovsky <i>et al.</i> , 1999, 2001; Yao <i>et al.</i> , 2006
STAT6	Mouse	Germline knockout	Viable	Impaired lymphoid development and differentiation Defective Th2 polarization, and IgG and IgE class switching; increased susceptibility to parasite infection Protection from allergic inflammation	IL-4; IL-13.	Shimoda <i>et al.</i> , 1996; Takeda <i>et al.</i> , 1996a,b; Urban <i>et al.</i> , 1998; Akimoto <i>et al.</i> , 1998; Kuperman <i>et al.</i> , 1998
CIS	Mouse	Germline knockout Conditional: T cells	Viable	Airway inflammation and increased susceptibility to experimental asthma. Enhanced generation of Th2 and Th9 T cell subsets	IL-2; IL-4.	Yang <i>et al.</i> , 2013
SOCS1	Mouse	Germline knockout	Perinatal lethality. Can be rescued by crossing KOs with mice deficient for IFN γ , IFN α receptor, Stat1 or Stat6	Multi-organ inflammatory infiltrate	Type I IFN; IFN γ ; IL-4; γ_c cytokines	Alexander <i>et al.</i> , 1999; Davey <i>et al.</i> , 2005; Cornish <i>et al.</i> , 2003; Starr <i>et al.</i> , 1998; Naka <i>et al.</i> , 2001; Fenner <i>et al.</i> , 2006

SOCS2	Mouse	Conditional: T cells Germline knockout	Viable	Gigantism	Growth hormone; prolactin	Chong <i>et al.</i> , 2003 Metcalf <i>et al.</i> , 2000
SOCS3	Mouse	Germline knockout	Embryonic lethality at E12-16	Placental deficiency as a result of excessive LIF signaling	gp130 cytokines; G- CSF; leptin; IL-12	Robb <i>et al.</i> , 2005; Takahashi <i>et al.</i> , 2003
		Conditional: hematopoietic and endothelial cells	Lethal as young adults	Inflammation in lung and peritoneal cavities		Croker <i>et al.</i> , 2003, 2004; Lang <i>et al.</i> , 2003
		Macrophages and neutrophils	Viable			
		'Knock-in' gp130Y757F mice (no SOCS3 recruitment)	Viable	Inflammatory joint disease		Yasukawa <i>et al.</i> , 2003a
SOCS4	Mouse	ENU-mutant	Viable	Increased susceptibility to influenza infection		Kedzierski <i>et al.</i> , 2014
SOCS5	Mouse	Germline knockout	Viable	No described phenotype		Brender <i>et al.</i> , 2004; Khaled <i>et al.</i> , 2007
SOCS6	Mouse	Germline knockout	Viable	Mild mammary gland hyperplasia		Krebs <i>et al.</i> , 2002
SOCS7	Mouse	Germline knockout	Perinatal lethality (C57BL/6)	Mild growth retardation		Krebs <i>et al.</i> , 2004; Banks <i>et al.</i> , 2005
			Viable (129/SvJ)	Hydrocephaly		
				Enhanced insulin signaling and improved glucose tolerance		

Figure 1 The JAK–STAT–SOCS signaling cascade. Cartoon representation of (a) JAK activation, (b) STAT activation, and (c) SOCS3 inhibition of JAK activity. (d–f) Schematics showing the generic domain architecture for JAK, STAT, and SOCS3 together with the three-dimensional crystal structures for (d) TYK2 FERM and SH2 (residues 23–583) in complex with a Box 2 peptide from IFNAR1 (residues 465–512) (Wallweber *et al.*, 2014) (pdb4po6), Tyk2 JH2 and JH1 (residues 566–1187) (Lupardus *et al.*, 2014) (pdb4OLI) domains; (e) unphosphorylated (Mao *et al.*, 2005) (pdb1yvl) and phosphorylated Stat1 dimer core (residues 132–713) bound to DNA (Chen *et al.*, 1998) (pdb1bf5); (f) SOCS3–SH2 domain (residues 22–185) bound to the gp130 phosphotyrosine peptide (residues 750–764) and JAK2 JH1 domain (Kershaw *et al.*, 2013) (pdb4GL9). The SOCS3–SOCS box–Elongin BC complex with Cullin5 and Rbx2 is a model created by juxtaposition of the following structures: SOCS2/BC/Cullin5 (pdb4JGH), Cullin5 N-terminal domain (pdb2WZK), Cullin5 C-terminal domain/Rbx2 (pdb3DPL). CCD, Coiled-coil domain; DBD, DNA binding domain; NT, N-terminal domain; SB, SOCS box.

Intriguingly, studies of each of the JAK tyrosine kinase (JH1) domains *in vitro* have not revealed any clear substrate specificities beyond a preference for acidic residues adjacent to the substrate tyrosine (Sanz *et al.*, 2011), a finding typical of tyrosine kinase domains when divorced from their regulatory domains. This then begs the question: if not solely via the substrate preferences of the catalytic, tyrosine kinase domain, how do JAKs achieve specificity in signaling? And secondly, if the tyrosine kinase domains of the four JAKs have overlapping

substrate specificities (Blouin *et al.*, 2011), why have four JAKs, rather than one evolved?

Our understanding of the capacity of JAKs to impart specificity in signaling has been greatly advanced by the development of knockout mouse models for each of the JAK family members (Table 1). Of note, JAK1, JAK2, and TYK2 are ubiquitously expressed, and only JAK3 expression is restricted to hematopoietic tissues, including the spleen, bone marrow, fetal liver, bone marrow and thymus, lymphoid and myeloid

cell lineages (Johnston *et al.*, 1994; Musso *et al.*, 1995; Witthuhn *et al.*, 1994). As a result, the ubiquity of JAK expression offers no solution to the origin of specificity. However, the phenotypes of mice genetically deleted for each JAK provide important insights into specificity. Firstly, the lethality of *Jak2*^{-/-} mice around embryonic day 12.5 demonstrates that JAK2 serves nonredundant functions in signaling that are not compensated for by JAK1, JAK3, and TYK2 (Neubauer *et al.*, 1998; Parganas *et al.*, 1998). Studies of fetal liver cells derived from *Jak2*^{-/-} mice revealed deficits in signaling downstream of several cytokine receptors (Table 1) and, relatedly the observed embryonic lethality was attributed to an absence of definitive erythropoiesis (Neubauer *et al.*, 1998; Parganas *et al.*, 1998). An essential role of JAK2 beyond embryonic development was underscored by conditional deletion of JAK2 in postnatal day 4 and adult mice (Akada *et al.*, 2014; Park *et al.*, 2013), where systemic deletion of JAK2 led to lethality due to defects in erythropoiesis, thrombopoiesis, hematopoietic stem cell maintenance and consequent bone marrow failure. While some cytokine receptors have evolved obligate relationships with effector JAKs (Table 1), others appear to have evolved promiscuous relationships and can equally utilize a subset or all JAK family members for signaling. This is evidenced by the granulocyte-colony stimulating factor receptor (G-CSFR), which exhibits no deficits in signaling upon deletion of *Jak1*, *Jak2*, or *Tyk2*, suggesting a redundancy where each JAK family member can signal equivalently downstream of G-CSFR activation.

These findings illustrate that, in many cases, cytokine receptors have developed obligate relationships with the JAK effectors they utilize, which cannot simply be accounted for by tissue-specific expression of the paralogs. Instead, there appears to be a biochemical, rather than biological, basis for the preference of receptors for JAKs. Two sequence motifs, termed Box 1 and Box 2, have been identified within the cytoplasmic portions of cytokine receptors and shown to function variably in JAK recruitment and activation. Box 1 is characterized by a consensus $\Pi\text{ITPV}[I/V]\text{PxP}[E/K]$ sequence (where Π is any hydrophobic residue), which is typically located in the intracellular juxtamembrane region, 6–10 residues C-terminal to the transmembrane domain (Tanner *et al.*, 1995; Usacheva *et al.*, 2002). Box 2, in contrast, is less well conserved and is characterized by a hydrophobic-charged-hydrophobic-hydrophobic motif, such as LEVL or VEVI. Relative to Box 1, the position of the Box 2 motif is highly variable, as exemplified by a Box 2 sequence positioned 7 residues C-terminal of Box 1 in IFNAR2, but 31 residues C-terminal to Box 1 in gp130 (Usacheva *et al.*, 2002). Broadly, these motifs can be thought to serve as recruitment sites for the JAKs via their FERM (JH7-JH4) domains. Typically, the function of JAK recruitment has been attributed to Box 1 in class I cytokine receptors, such as growth hormone receptor (GHR), EPOR, gp130, and beta common (β_c), with Box 2 believed to function in JAK activation rather than binding. Among the class II cytokine receptors, however, there is wide variability in the conservation and function of Box 1 and Box 2 motifs. Indeed, IFNGR1 and the IL-10R α have no apparent motif that conforms to the above Box 1 and Box 2 consensus sequences (Usacheva *et al.*, 2002), yet still bind and signal via JAK1 (Table 1). The absence of strict rules governing JAK recruitment by the receptors is

hardly surprising if one considers that each receptor system has coevolved with JAKs to permit combinatorial use of different JAK family members to enable signal pleiotropy. For example, both JAK1 and JAK3 are utilized as effectors downstream of γ_c receptor activation (Table 1), and as such the receptor has evolved motifs that enable binding of both JAKs, whereas GHR signals strictly via JAK2 and has thus evolved the capacity to strictly bind JAK2. In 2014, the first detailed insights into receptor binding by the JAKs were provided by the crystal structure of the TYK2 FERM-SH2 (JH7-3) domains in complex with the IFNAR1 Box 2 motif (Wallweber *et al.*, 2014; Figure 1(d)). This work revealed that the F1 lobe of the FERM domain intimately interacts with the SH2 domain, thereby positioning the SH2 domain adjacent to the F2 lobe of the FERM domain to form a composite Box 2 binding motif. Interestingly, the SH2 domain contains a His (H474) in place of the canonical phosphotyrosine binding Arg, consistent with a non-phosphotyrosine binding function. Instead, the adjacent residues, S476 and T477, were shown to form two hydrogen bonds with the carboxylate of the IFNAR1 Box 2 residue, E497: an interaction essential for complexation. Whether similar interactions are likely to occur between other JAKs and the receptors, especially in cases where Box 1 is the primary recruitment motif, awaits further structural characterization.

Mechanism of Activation

These receptors assemble into oligomeric structures and thereby act as scaffolds to recruit two (or more) JAK family proteins. Prior to receptor activation, the receptor-bound JAK kinases are maintained in an inactive state (Figure 1(a)). Upon ligation of the receptor ectodomains by a cognate cytokine ligand, the receptor subunits are reoriented, with this motion conveyed from the ectodomain, across the transmembrane domain, into the intracellular region. The resulting repositioning of the intracellular regions of the receptor subunits is believed to simultaneously reposition the receptor-associated JAKs to enable phosphorylation of one another and consequent activation (Figure 1(a)). It has long been established from biochemical studies that maximal catalytic activity by the JAK family tyrosine kinase domains depends on the trans-phosphorylation of the activation loop tyrosine residues (Chatti *et al.*, 2004). Inhibition of JAK catalytic activity prior to receptor activation can be attributed to the pseudokinase (JH2) domain, which recent data suggest acts *in trans* to suppress tyrosine kinase domain activation (Figure 1(a); Brooks *et al.*, 2014; Koppikar *et al.*, 2012; Varghese *et al.*, 2014). The functions of pseudokinase domains are still emerging (Murphy *et al.*, 2014) and there appears to be subtle differences between the functions of those within the JAK family. For example, the pseudokinase domain of JAK2 has been shown to exhibit a weak catalytic function (Bandaranayake *et al.*, 2012; Ungureanu *et al.*, 2011) that enables phosphorylation of negative regulatory sites: S523 in the SH2-pseudokinase domain linker and Y570 within the pseudokinase domain (Bandaranayake *et al.*, 2012; Ishida-Takahashi *et al.*, 2006; Mazurkiewicz-Munoz *et al.*, 2006; Ungureanu *et al.*, 2011). In contrast, the counterpart domain in JAK1 exhibited no detectable catalytic activity (Toms *et al.*, 2013) and the TYK2

pseudokinase domain did not detectably bind ATP (Murphy *et al.*, 2014). These data argue for the JAK pseudokinase domains principally serving catalysis-independent functions to inhibit the catalytic activities of the tyrosine kinase domains. The function of the JAK2 pseudokinase domain as a suppressor of the tyrosine kinase domain is well established (Saharinen and Silvennoinen, 2002; Saharinen *et al.*, 2000, 2003), and human myeloproliferative neoplasms have been attributed to mutations within the pseudokinase domain, exemplified by the V617F mutation first reported in 2005 (Zhao *et al.*, 2005; Levine *et al.*, 2005; James *et al.*, 2005; Kralovics *et al.*, 2005; Baxter *et al.*, 2005).

Recent work has laid a platform for understanding how the JAK pseudokinase domain can suppress the catalytic activity of the JAK tyrosine kinase domain. Many models have been generated in the absence of experimental support in which the pseudokinase domain was proposed to bind and suppress the adjacent tyrosine kinase domain *in cis*. In the case of JAK2, however, recent experimental data supports the existence of the pseudokinase–kinase tandem domains in an elongated conformation. Firstly, recombinant pseudokinase–kinase tandem domains expressed and purified from insect cells were phosphorylated at Y1007/Y1008, a hallmark of JAK2 activation, illustrating a limited capacity for the pseudokinase domain to bind and inhibit the catalytic activity of the adjacent kinase domain *in cis* (Varghese *et al.*, 2014). Further, rather than a condensed conformation in which an intimate association between the pseudokinase and tyrosine kinase domains mediates inhibition of catalytic activity, small-angle X-ray scattering studies supported the idea that, in solution, the JAK2 pseudokinase–kinase tandem domains exist in an extended conformation (Figure 1(d); Varghese *et al.*, 2014). JAK1 was similarly observed to adopt an elongated conformation in cryo-electron microscopy studies (Lupardus *et al.*, 2011).

These data are consistent with an attractive model that has recently been proposed based on experimental studies of JAK2 activation downstream of the GHR (Brooks *et al.*, 2014). This model is based on the observation that GHR ligation by GH results in a relative rotation of receptor subunits, which, based on mutational and crosslinking studies, was modeled to be transmitted via the helical transmembrane domains to the intracellular, helical juxtamembrane region and Box 1 motif. Unexpectedly, by fusing FRET probes either C-terminal to the GHR Box 1 motif or C-terminal to the JAK2 pseudokinase or kinase domain and monitoring their positions following GHR activation (Brooks *et al.*, 2014), it was proposed that the JAK2 molecules associated with each of the two receptor subunits are drawn apart, rather than into proximity as previously believed. Based on modeling, crosslinking and biochemical studies, other homodimeric class I cytokine receptors, such as EPOR and c-Mpl, were similarly proposed to contain helical regions adjacent to Box 1 in their juxtamembrane regions (Staerk *et al.*, 2011; Seubert *et al.*, 2003). Taken together these studies suggest a concerted model for JAK2 activation following homodimeric receptor activation, although the extent to which the same rules apply to the more complicated, heteromeric class I and class II cytokine receptors remains to be established.

Furthermore, it is unclear whether the proposed mechanism of JAK2 activation is likely to be conserved among all JAK family members. While JAK1 was found to exist in an

elongated conformation with no fixed pseudokinase:kinase orientation (Lupardus *et al.*, 2011), an observation consistent with a JAK2-like activation mechanism, the opposite has been proposed for TYK2 (Lupardus *et al.*, 2014). The recent crystal structure of TYK2 pseudokinase–kinase tandem domains suggests the two domains intimately interact via their N-lobes in a back-to-back arrangement (Figure 1(d)). This idea is supported by the observation that within the context of the purified recombinant TYK2 pseudokinase–kinase, the kinase domain activation is suppressed, and mutations that are predicted to perturb the interaction of the pseudokinase and kinase domains relieve this suppression (Lupardus *et al.*, 2014). These data, and the observation that the TYK2 pseudokinase–kinase domain linker is 14 residues shorter than the equivalent sequence in JAK2, raise the possibility that an *in cis* mode of pseudokinase-mediated kinase domain inhibition could predominate in TYK2, while the longer interdomain linker favours *in trans* inhibition in JAK2. The precise details of these mechanisms await further detailed structural analyses.

Signaling Downstream of JAK Activation

Following ligation of receptors by their ligands, receptor-associated JAK molecules are opposed to facilitate their activation by *trans*-phosphorylation. Principally, the activation is thought to comprise mutual phosphorylation of their kinase domain activation loops on a Tyr-Tyr motif, where phosphorylation of the first of these Tyr residues (Y1007 in JAK2) is known to be essential for elevated catalytic activity (Chatti *et al.*, 2004; Feng *et al.*, 1997). Following JAK activation, however, the precise details of how JAKs activate further signaling pathways remain unclear. Many tyrosines within receptor intracellular regions have been identified as JAK substrates and their phosphorylation is known to enable recruitment of phosphotyrosine binding-domain containing effectors to the receptor, including the STATs, as detailed in the next section. The outstanding questions remain: why have JAKs evolved as non-receptor tyrosine kinases rather than RTKs and, relatedly, do JAKs serve functions in addition to their roles as cytokine receptor effectors? One answer to these questions may come from studies attributing a nuclear function to JAKs, where divorced from cytokine receptors, JAK2 has been reported to phosphorylate histone H3 in the nucleus (Dawson *et al.*, 2009). On the other hand, convincing evidence for non-cytokine receptor based cytoplasmic functions of JAKs has yet to emerge. In fact, JAK1 phosphorylation following LIF receptor activation induced dissociation from the receptor, a step that was found to promote its proteasomal degradation via the negative regulator, SOCS3 (Boyle *et al.*, 2009). These findings suggest that rather than activated JAKs serving non-receptor, cytoplasmic signaling functions, mechanisms exist within the cell to eliminate activated JAKs once dissociated from their receptors. These and other negative regulatory mechanisms are outlined below.

STAT Proteins

The STAT proteins are characterized by a unique ability to transduce a signal from the receptor complex at the membrane

to the nucleus, where they function as transcription factors, inducing an appropriate program of gene expression. Conceptually, this makes the JAK-STAT pathway one of the simpler, and perhaps more efficient, signaling cascades.

The STAT proteins exist in the cytoplasm as preformed dimers and are recruited to the receptor complex following ligand binding, JAK activation, and phosphorylation of key tyrosine motifs within the receptor cytoplasmic domains. They bind to the receptor phosphotyrosine residues via their SH2 domains and become 'second tier' substrates for phosphorylation by the JAK kinases. Phosphorylation occurs on a key conserved tyrosine in the C-terminal STAT tail and induces a major change in the configuration of the dimer (antiparallel to parallel); stabilized by SH2 binding to the reciprocal STAT tyrosine residue. As a consequence, the STATs disengage from the receptor complex and translocate to the nucleus, traversing the nuclear pore complex with the assistance of various transport receptors, commonly referred to as importins (Liu *et al.*, 2005). Once in the nucleus they bind to promoter elements to induce gene transcription.

There are seven STAT family members: STAT1, 2, 3, 4, 5A and 5B, and STAT6. All contain amino-terminal (NT), coiled-coil (CCD), DNA binding (DBD) and linker regions, in addition to an SH2 domain and a C-terminal conserved tyrosine residue and transactivation domain (TAD) (Figure 1(e)). A number of differentially spliced isoforms exist for STAT1, STAT3, STAT4, and STAT5 that result in truncation of the C-terminal tail (Darnell *et al.*, 1994; Hoey *et al.*, 2003; Wang *et al.*, 1996), while STAT5A and 5B are the products of a gene duplication event (Liu *et al.*, 1995).

SH2 domains are approximately 100 amino acids in length and have the ability to bind phosphotyrosine residues that are contained within specific sequence motifs. In general, different SH2 domains will bind different motifs. STAT recruitment to different receptor complexes is determined by STAT-SH2 domain recognition of the residues located adjacent to the receptor phosphotyrosines. The result is ligand-dependent activation of the various STAT proteins (Heim *et al.*, 1995) and is consistent with their distinct biological roles, which for the most part, have been elucidated by the generation and analysis of STAT-deficient mice. For example, STAT1 is recruited to both the IFN γ receptor (IFNGR1) (Y440) (Greenlund *et al.*, 1995) and the IFN α/β receptor (IFNAR1) (Y510) (Zhao *et al.*, 2008) receptors. Accordingly, *Stat1*-deficient mice are susceptible to infection by both bacterial and viral pathogens due to an inability to signal via type I and type II IFNs (Meraz *et al.*, 1996; Durbin *et al.*, 1996). Type I IFNs also signal through STAT2 and *Stat2*-deficient mice are similarly highly susceptible to viral infection. G-CSF, leptin, and gp130 cytokines signal through STAT3, IL-4 and IL-13 through STAT6, IL-12 and IL-23 via STAT4 and the IL-2 family cytokines, IL-3, GM-CSF, EPO, prolactin, and GH signal through STAT5 (Table 1).

The STAT proteins can form homo- or heterodimers, each complex initiating a unique pattern of gene transcription. STAT1, STAT3, STAT4, STAT5, and STAT6 all function as homodimers. The STAT1 homodimer was originally described as a gamma-activated factor (GAF). STAT1 and STAT3 can additionally form a heterodimer, while STAT2, together with STAT1 and IRF9, forms a heterotrimeric transcription complex, which is often referred to as ISGF3 (IFN-stimulated gene 3;

reviewed in Fink and Grandvaux, 2013). STAT2 is also thought to have some STAT1-independent functions (Hahm *et al.*, 2005; Perry *et al.*, 2011).

STAT signaling within the cell is in constant flux; both phosphorylated and unphosphorylated STAT dimers can enter the nucleus and both can induce gene transcription. However, the import and export of STAT proteins from the nucleus appears to be differentially regulated within the STAT family (Reich, 2013). At least in the context of STAT1, the phosphorylated 'parallel' dimer is actively trafficked into the nucleus, is able to bind to specific DNA sequences and is slower to exit the nucleus, resulting in cytokine-driven signaling responses. That is not to say that 'unphosphorylated' STAT-driven transcription is not without biological consequence, as is evident from the transcriptional profiles observed in various cancers where STAT3 is elevated (Yang *et al.*, 2005) (discussed below).

In general, the STAT dimers bind to a palindromic core sequence: TTC(N)₂₋₄GAA (Xu *et al.*, 1996; Schindler *et al.*, 1995) in the promoter regions of target genes, but have preferences for the spacing between the two halves of the palindrome, with STAT1-5 preferring N₃, while STAT6 prefers N₄ (Ehret *et al.*, 2001). The two STAT molecules form a clamp-like structure which is held together by the reciprocal SH2:phosphotyrosine interactions, while the two DNA binding domains sandwich the DNA core (Chen *et al.*, 1998; Figure 1(e)). Interactions between the NT regions of adjacent STAT dimers stabilize binding to neighboring sites (Vinkemeier *et al.*, 1996; Xu *et al.*, 1996) and can also facilitate the recruitment of additional STAT1 dimers in the absence of multiple GAF sites. This latter results in a cooperative mode of binding that is required for STAT1 transcriptional responses to type II IFN but strikingly, not for type I IFN responses mediated by the ISGF3 complex (Begitt *et al.*, 2014), and provides a molecular explanation for the different transcriptional profiles generated by STAT1-containing complexes.

The key serine in the transactivator domain of STAT1, 3, 4, and 5 can be phosphorylated by various serine kinases and phosphorylation is required for full transcriptional activity (Wen *et al.*, 1995; Visconti *et al.*, 2000). Consequently, the truncated STAT isoforms appear to function as dominant negatives (Wang *et al.*, 1996). De-phosphorylation of STAT proteins is a prerequisite for STAT exit from the nucleus. This is best illustrated by the role of the nuclear phosphatase TC45 in STAT1 de-phosphorylation (ten Hoeve *et al.*, 2002).

The unphosphorylated dimer is stabilized by two interfaces, one between the NT regions and a reciprocal interaction between the CCD and DBD (Figure 1(e); Mao *et al.*, 2005). The contribution of the unphosphorylated STAT dimers to signaling has steadily emerged over the past few years. STAT genes are often the transcriptional targets of active STAT dimers, with the net result being an increase in the pool of unphosphorylated STAT proteins. At least for STAT1 and STAT3, it is apparent that this can drive a secondary wave of transcription that is distinct from the canonical STAT response. This has a biological context with, for instance, the prolonged transcription of antiviral genes sustaining immunity to a chronic infection (Cheon and Stark, 2009).

There are also implications for cancers, where in addition to the activation of STAT3 by cytokines and oncogenic tyrosine

signaling cascades, reviewed in (Ernst and Putoczki, 2012; Yu *et al.*, 2009), increased expression of the unphosphorylated STAT3 pool can enhance the transcription of tumor-promoting genes (Yang *et al.*, 2005). The unphosphorylated dimers are proposed to activate gene transcription via binding to NF- κ B (Yang *et al.*, 2007), although there is now some evidence that they can bind directly to DNA (Nkansah *et al.*, 2013). The ability of unphosphorylated STAT proteins to stabilize heterochromatin and regulate three-dimensional chromatin structure, is also an area of interest (Shi *et al.*, 2008; Zhao *et al.*, 2013; Hu *et al.*, 2013).

Finally, independent of their classic transcriptional activity in the nucleus, there is an emerging role for STAT proteins in mitochondria, reviewed in (Meier and Larner, 2014). STAT3 is found associated with mitochondrial electron transport chain complexes where it promotes cellular respiration (Wegrzyn *et al.*, 2009) and can contribute to Ras-mediated oncogenesis (Gough *et al.*, 2009). STAT5 also appears to have a non-canonical role in maintaining the structural integrity of the Golgi apparatus and endoplasmic reticulum (Lee *et al.*, 2012).

Among the key genes induced by phosphorylated STAT dimers is an important family of small cytoplasmic inhibitors, the SOCS proteins.

The SOCS

Once activated, it is important that the JAK/STAT signaling cascade is switched off after an appropriate duration. This is both to prevent excessive proliferation in response to cytokine as well as to allow the cell to return to its basal state, ready for subsequent rounds of stimulation. The primary effectors responsible for this temporal control are the SOCS family. SOCS expression is induced by the JAK/STAT cascade and they act as components of a negative feedback loop to shut down signaling (Endo *et al.*, 1997; Naka *et al.*, 1997; Starr *et al.*, 1997).

The SOCS family consists of eight proteins in humans, SOCS1-7 and CIS (Hilton *et al.*, 1998). These eight family members are the descendants of three ancestral SOCS proteins (SOCS1/2/3/CIS; SOCS4/5, SOCS6/7), also found in extant organisms such as sea anenomes (Liongue and Ward, 2013). Of these, the first subgroup in particular (containing SOCS1, SOCS2, SOCS3, and CIS) have all been shown to strongly inhibit JAK/STAT signaling; their expression is induced by activated STATs and they then inhibit the cytokine-induced JAK/STAT signaling cascade. SOCS4 and SOCS5 also play a role in inhibition of JAK/STAT signaling (Linossi *et al.*, 2013) whilst, in contrast, SOCS6 and SOCS7 appear to regulate receptor tyrosine kinase (RTK) signaling pathways (Krebs *et al.*, 2002; Banks *et al.*, 2005; Bayle *et al.*, 2004; Zadjali *et al.*, 2011).

SOCS proteins all share a similar domain architecture consisting of an N-terminal domain, a central SH2 domain and a C-terminal SOCS box domain (Figure 1(f)). The SOCS box domain is a small ~40 amino acid domain consisting of 2–3 alpha helices and contains two separable binding motifs. The first, contained in the N-terminal half of the domain, binds the adapter complex elonginBC (Zhang *et al.*, 1999; Kamura *et al.*, 1998) whilst the second, an L-P-L-P motif found in the C-terminal half of the domain binds the E3 ligase scaffold protein Cullin5 (Kamura *et al.*, 2004; Muniz *et al.*,

2013; Babon *et al.*, 2008, 2009). E3 ubiquitin ligases catalyze the ubiquitination of substrate proteins and the eight SOCS proteins can be considered the substrate recruitment modules for Cullin5-based E3 ligases, conveying substrates to the multi-subunit ligase in order for them to be ubiquitinated. The majority of these substrates are believed to be cytokine receptors (Irlandoust *et al.*, 2007; Metcalf *et al.*, 2000; Kershaw *et al.*, 2014; Qing *et al.*, 2005; Landsman and Waxman, 2005; Lavens *et al.*, 2006) and their ubiquitination leads either to proteosomal degradation (Kamizono *et al.*, 2001) or lysosomal routing (Irlandoust *et al.*, 2007) thus inhibiting JAK/STAT signaling by removing the activated cytokine receptor, and potentially their associated JAKs. The SOCS box is the defining feature of the eight SOCS family members but is also found in a much larger family of proteins, all of which act as substrate recruitment modules for E3 ubiquitin ligases (Hilton *et al.*, 1998; Kile *et al.*, 2002; Linossi and Nicholson, 2012).

SOCS1 and SOCS3

SOCS1 and SOCS3 are arguably the most potent inhibitors of cytokine signaling within the SOCS family. Their expression is highly upregulated within 15–30 minutes (Wormald *et al.*, 2006) of exposure to cytokine and they then rapidly inhibit signaling, approximately halving the duration of the signaling cascade that would occur in their absence (Wormald *et al.*, 2006). Although induced by a multitude of different cytokines and capable of inhibiting an almost equal number (when artificially overexpressed), knockout studies have shown that SOCS1 and SOCS3 are highly specific inhibitors of just a handful of different cytokines under normal, physiological conditions (Table 1).

Genetic deletion of either SOCS1 or SOCS3 is lethal (Roberts *et al.*, 2001; Alexander *et al.*, 1999; Table 1). *Socs1*^{−/−} mice die a few weeks after birth from an inflammatory disease due to dysregulated IFN γ signaling (Alexander *et al.*, 1999). This disease can be rescued by genetic deletion of IFN γ and partially alleviated by deletion of STAT1 or STAT6, although the resultant animals still develop a fatal inflammatory disease and die earlier than wild-type littermates (Naka *et al.*, 2001; Alexander *et al.*, 1999). In addition to IFN γ signaling, genetic deletion studies have shown that SOCS1 is also a potent inhibitor of IFN α/β (Gingras *et al.*, 2004; Fenner *et al.*, 2006), IL-12/23 (Eyles *et al.*, 2002), IL-4/IL-13 (Naka *et al.*, 2001) and cytokines that signal through the γ_c chain (IL-2, 15, 21) (Davey *et al.*, 2005).

Socs3^{−/−} embryos are non-viable due to defects in placenta (Roberts *et al.*, 2001), a phenotype that can be rescued by simultaneous genetic deletion of LIF (Robb *et al.*, 2005), however the resultant mice still die as young adults from a fatal inflammatory disease. Conditional knockout of SOCS3 in restricted cell types has shown it to be specific for IL-6 family cytokines (Yasukawa *et al.*, 2003b), G-CSF (Crocker *et al.*, 2004), and leptin (Mori *et al.*, 2004).

Direct Kinase Inhibition by SOCS1 and SOCS3

In addition to acting as E3 ubiquitin ligases (Kershaw *et al.*, 2014), SOCS1 and SOCS3 directly inhibit the catalytic activity

of JAKs, via the action of their so-called 'kinase inhibitory regions' (KIRs) (Figure 1(c)). The KIR was first identified by the groups of Yoshimura (Sasaki *et al.*, 1999; Yasukawa *et al.*, 1999) and Kishimoto (Narazaki *et al.*, 1998) as a short region in the N-terminal domain of SOCS1 and SOCS3, immediately upstream of their SH2 domains. Recent structural studies have shown that the KIR is unstructured in the absence of JAK (Babon *et al.*, 2005, 2006) yet becomes structured in its presence, where it binds to the substrate-binding groove of the JAK catalytic domains and prevents substrate binding (Kershaw *et al.*, 2013). This inhibits further downstream signaling. Inhibition of signaling by this direct kinase inhibitory mechanism is the dominant mode-of-action of both SOCS1 and SOCS3, as genetic deletion of their SOCS boxes (and hence abrogation of their ability to induce ubiquitination of any substrates) causes a much milder phenotype than the full knockout (Zhang *et al.*, 2001; Boyle *et al.*, 2007). SOCS3 is capable of inhibiting JAK1, JAK2 and TYK2 via this mechanism but not JAK3, due to the absence of a conserved sequence element in the JAK3 kinase domain (Babon *et al.*, 2012). The JAK targets of SOCS1 are currently unknown.

Although capable *in vitro* of inhibiting three of the four JAK family members, SOCS3 is a specific inhibitor of only a small subset of cytokines *in vivo*. This is because SOCS3 can bind JAK and cytokine receptor simultaneously, via two different molecular surfaces (Kershaw *et al.*, 2013). The phosphotyrosine-binding groove of its SH2 domain binds to receptor whilst the opposing surface of its SH2 domain, along with the KIR, binds JAK (Figure 1(f)). Only receptors containing the correct phosphotyrosine-based motifs are targeted with high affinity. The true target of SOCS is therefore a JAK-cytokine receptor complex, rather than a JAK or receptor alone. This allows for specific, and potent, inhibition of cytokines that signal via receptors that (A) bind JAK1, JAK2, or TYK2 and (B) contain the correct phosphotyrosine-based binding sites. Cytokines that fulfill these two criteria are leptin (De Souza *et al.*, 2002), G-CSF (Hortner *et al.*, 2002), and IL-6 family cytokines (Nicholson *et al.*, 2000) (reviewed in Babon and Nicola, 2012). The JAK- or receptor-binding specificities of SOCS1 are currently unclear but it may act via a similar mechanism.

SOCS2 and CIS

SOCS2 and CIS, like SOCS1 and SOCS3, consist primarily of only SH2 and SOCS box domains, having only very short N-terminal regions. However, unlike SOCS1 and SOCS3, these two proteins do not contain a kinase inhibitory region and therefore rely entirely upon their ability to ubiquitinate substrates in order to inhibit JAK/STAT signaling. Consistent with this, *in vitro* studies have shown that both SOCS2^{ΔSB} and CIS^{ΔSB} (which lack the SOCS Box) act as dominant negatives (Greenhalgh *et al.*, 2005; Ram and Waxman, 2000). SOCS2 binds to phosphorylated growth hormone receptor (at pY595) (Bullock *et al.*, 2006, 2007) and induces its ubiquitination. Consistent with this, *Socs2*^{-/-} mice display gigantism due to dysregulated growth hormone signaling (Metcalf *et al.*, 2000). *Cis*^{-/-} mice are born healthy but have recently been shown to suffer a spontaneous lung disease, similar to that of allergic

asthma (Yang *et al.*, 2013) due to dysregulated IL-4 signaling. The molecular determinants of CIS action are yet to be determined.

SOCS4 and SOCS5

The involvement of SOCS4 and SOCS5 in regulation of JAK/STAT signaling is less well understood than for SOCS1, SOCS2, SOCS3 and CIS. In addition to a role in JAK/STAT signaling both SOCS4 and SOCS5, as well as their *Drosophila* homolog (SOCS36E) have been shown to regulate EGF signaling (Callus and Mathey-Prevot, 2002; Rawlings *et al.*, 2004; Nicholson *et al.*, 2005; Kario *et al.*, 2005). In mammals, SOCS5 has been implicated in the regulation of IL-4 signaling (Seki *et al.*, 2002) whilst little is known of the actions of SOCS4. Both SOCS4 and SOCS5 are highly similar at the amino acid level, especially across their SH2 domains and a structured segment within their large N-terminal domains (Feng *et al.*, 2012) which suggests they may have similar molecular targets. Despite this, recent studies have shown that SOCS5 can inhibit JAK1 and JAK2 autophosphorylation whereas SOCS4 cannot (Linossi *et al.*, 2013; Figure 1).

JAK-STAT-SOCS and Human Disease

Involvement of JAK Proteins in Human Disease

Inherited mutations in JAK3 and TYK2 can result in human immune deficiency syndromes. JAK3 is exclusively associated with the common γ -chain receptor that is utilized by cytokines required for T- and NK cell production and function including IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21. Bi-allelic inherited mutations in either JAK3 (7–14% of patients) or the common gamma chain are associated with severe combined immunodeficiency syndrome (SCID) with the latter the most common in X-linked SCID. The JAK3 mutations occur throughout the coding sequence and generally result in a complete loss of protein production and absence of T- and NK but not B-cells (O'Shea *et al.*, 2013). TYK2 associates with IFN α/β and IL-6 receptors and mutations have been described in two patients. Both showed severe herpes virus infection and mycobacterial infection but differed in other clinical features, suggesting a common deficiency in IFN signaling, but also unique features such as hyper IgE that may be due to different genetic backgrounds (Kilic *et al.*, 2012; Minegishi *et al.*, 2006).

Several activating mutations in JAK2 have been associated with myeloproliferative neoplasms (MPN), chronic and acute myeloid and lymphoid leukemias. In several chromosomal translocations the oligomerization domain of one partner is fused to the kinase domain (JH1) or both kinase and pseudokinase (JH2) domains of N-terminally truncated JAK2 (James *et al.*, 2005; Jatiani *et al.*, 2010). Constitutive dimerization of such fusion proteins is thought to allow cross-phosphorylation and activation of the JAK2 kinase domain. The fusion partners include the ETS domain of the transcription factor TEL, the centrosome-associating protein PCM1 and the GTPase-activating protein BCR and result in T-lymphocytic and myeloid leukemias; myeloid and lymphoid neoplasms;

and atypical chronic myeloid leukemia, respectively (Vainchenker and Constantinescu, 2013).

The MPNs, polycythemia vera (PCV), essential thrombocythemia (ET), and idiopathic myelofibrosis (MF) display a high frequency of somatically acquired activating mutations in JAK2. The most common mutations result in the V617F point mutation in the pseudokinase domain or are exon 12 mutations in the N-terminally adjacent domain of JAK2 (~100% in PCV, ~60% in ET, and ~60% in MF). These mutations result in a constitutively active kinase, although *in vitro* studies suggest that an appropriate homodimeric cytokine receptor (EPO, thrombopoietin, or G-CSF receptor) is required to activate mutant JAK2 and perhaps to scaffold other essential signaling molecules like STAT5. Additional mutations in negative regulators of JAK2 such as the lymphocyte-specific adaptor protein LNK or calreticulin mutations (in ~20% of ET and 20% of MF) are present in MPNs and result in constitutive JAK2 activation although the mechanisms are not clear (Cazzola and Kralovics, 2014). There is some evidence that particular mutations have selective effects on the disease phenotype, progression or outcome. For example, the JAK2 exon 12 mutations result in almost exclusive erythrocytosis (Scott *et al.*, 2007) and progression from ET to PV or PV to MF is associated with an increase in mutant allele burden (progression to homozygosity) (Cazzola and Kralovics, 2014). More rare activating mutations in the JH2 domain, such as point mutations of R683, have been associated with about 20% of acute lymphoblastic leukemias seen in patients with Down's syndrome (Mullighan and Downing, 2009).

Somatic activating mutations in the JAK1 JH2 domain have been detected in up to 20% of adult T-cell acute lymphoblastic leukemia (T-cell ALL) and less commonly in B-cell ALL (Flex *et al.*, 2008; Jeong *et al.*, 2008). Mutations in JAK1 have also been detected in AML and non-hemopoietic tumors but at a lower frequency. Finally, activating mutations located in the FERM or pseudokinase domains of JAK3 have also been detected in acute megakaryocytic leukemia (Walters *et al.*, 2006).

Involvement of STAT Proteins in Human Disease

A heterozygous dominant negative mutation in STAT1 was first described in a child susceptible to mycobacterial but not viral infections (Dupuis *et al.*, 2001) while homozygous STAT1 deficiency in other infants resulted in susceptibility to both infections (Dupuis *et al.*, 2003). This was due to failed IFN- γ signaling in the former case but failed IFN γ and IFN α signaling in the latter. Perhaps surprisingly, activating mutations in STAT1 have been associated with fungal infections possibly due to excessive IFN γ signaling but diminished IL-17 responses (Liu *et al.*, 2011; van de Veerdonk *et al.*, 2011).

Dominant negative mutations have also been found for STAT3 and result in hyper IgE syndrome with increased infections and some bone defects (Minegishi *et al.*, 2007; Holland *et al.*, 2007). Since STAT3 is essential for Th17 responses some of these defects appear to be due to diminished IL-17 responses (Milner *et al.*, 2008). Homozygous inactivating mutation of STAT5b in a child demonstrated growth retardation due to growth hormone insensitivity and autoimmune defects, apparently due to increased Th17 responses

resulting from lack of inhibition by IL-2 and reduced regulatory T cells (Kofoed *et al.*, 2003).

Constitutive activation of STAT3 has been associated with numerous solid (epithelial, liver, breast, prostate and melanoma) and hemopoietic tumors (CML, AML, CLL, ALL, multiple myeloma) (Bromberg, 2002). This probably reflects the common activation of STAT3 by growth-promoting tyrosine kinase receptors and by the tumor-promoting TH17-type inflammatory response in tumors as well as angiogenic signaling by STAT3. In contrast STAT1 activation is thought to promote antitumor immunity through a TH1-type response and is less frequently activated in tumors. Moreover, only STAT3 has been shown to be required for cancer cell line proliferation for both solid tumors and leukemias (Bromberg, 2002). On the other hand STAT5 seems to be the major STAT required for proliferation of myeloproliferative neoplasms induced by activating JAK2 mutations (Funakoshi-Tago *et al.*, 2010).

Activating STAT3 mutations (usually in the SH2 domain required for STAT dimerization) are relatively common (30–40%) in T cell large granular lymphocytic leukemia and NK cell leukemias (Ohgami *et al.*, 2013; Koskela *et al.*, 2012; Jerez *et al.*, 2012) and at lower frequency in a subset of diffuse B-cell lymphomas (Ding *et al.*, 2008).

Involvement of SOCS Proteins in Human Disease

Although there have been reports of increased expression of SOCS proteins associated with several diseases and in several tumor types (Trengeve and Ward, 2013) these studies are difficult to interpret because the expression of SOCS proteins is induced by cytokine signaling and in particular by STAT activation. Consequently, increased expression of SOCS may simply reflect activation of STAT pathways by alterations in the cytokine milieu or primary mutations in receptors or oncogenes that activate the JAK/STAT pathway with no causative relationship to disease. Similarly, although enforced expression of a SOCS protein may ameliorate disease this may represent an ability to dampen JAK/STAT signaling rather than reflecting loss of SOCS expression as a cause of disease.

It is more convincing that several studies have revealed a loss of SOCS1 or SOCS3 expression in a range of tumors and have correlated this with specific epigenetic regulation at the locus by bi-allelic methylation of the respective promoters or enhancers. These include high-frequency methylation of the SOCS1 gene in hepatocellular carcinoma (HCC 69%) (Yang *et al.*, 2003; Yoshikawa *et al.*, 2001), gastric carcinoma (GC 44%) (Oshimo *et al.*, 2004), myelodysplastic syndrome (MDS 31%) (Brakensiek *et al.*, 2005), ovarian cancer (23%) (Sutherland *et al.*, 2004), and pancreatic ductal adenocarcinoma (22%) (Fukushima *et al.*, 2003). Similarly, methylation of the SOCS3 gene has been reported in head and neck squamous cell carcinoma (90%) (Weber *et al.*, 2005), non-small cell lung cancer (80%) (He *et al.*, 2004), and HCC (30%) (Niwa *et al.*, 2005).

Inactivating somatic mutations in SOCS genes are rare but a significant proportion of classical Hodgkin Lymphoma patients (8/19) displayed a variety of inactivating mutations in SOCS1 resulting in enhanced nuclear accumulation of STAT5

(Weniger *et al.*, 2006) as did 9/20 primary mediastinal B-cell lymphomas (Melzner *et al.*, 2005).

Concluding Remarks

It has been quite a long journey over the last 20 years, as the intricacies of the JAK–STAT–SOCS network and the exquisite cellular control of this fascinating pathway have unfolded. Clearly there are many layers of regulation, extending from suppression of JAK activation by its pseudokinase domain, phosphorylation, and de-phosphorylation of the STATs and induction of the signaling suppressors, SOCS1 and SOCS3, which then act to directly inhibit JAK catalytic activity. The complexity of STAT action is only just beginning to be appreciated and includes their transit into and out of the nucleus and distinct roles in mitochondria. We are quite sure that there is still more to be discovered and eagerly await the next chapter in the story. Together, the multilayered regulation of the JAK–STAT pathway offers many entry points for therapeutic intervention in hematological diseases and solid tumors.

Families of Phosphoinoside-Specific Phospholipase C Enzymes

Phosphoinoside-specific phospholipase C (PLC) enzymes catalyze the hydrolysis of inositol lipids, mainly phosphatidylinositol 4,5-bisphosphate [PI(4,5)P₂] to inositol 1,4,5-trisphosphate (IP₃) and diacylglycerol (DAG) (Suh *et al.*, 2008; Gresset *et al.*, 2012; Kadamur and Ross, 2013; Figure 1(a)). The released IP₃ binds to IP₃ receptors on the endoplasmic reticulum resulting in Ca²⁺ release into the cytoplasm. DAG remains in the membrane and activates some isoforms of protein kinase C (PKC), other kinases, and GTPase regulating proteins (Brose and Rosenmund, 2002). Other functions of PI(4,5)P₂ are related to its interactions with a number of proteins, particularly ion channels and proteins involved in the actin cytoskeleton (Suh and Hille, 2008; Lemmon, 2008). PLC enzymes could impact on these interactions by changing local concentrations of PI(4,5)P₂.

There are six families of PLC enzymes (PLC β , δ , γ , ϵ , η , and ζ) and 13 human isoforms in total (β 1–4, δ 1, 3 and 4, γ 1 and 2, ϵ 1, η 1 and 2 and ζ 1); some isoforms also have splice variants (Suh *et al.*, 2008). With respect to regulatory mechanisms, the most extensive insights have been obtained for activation of PLC β family by G-protein coupled receptors (GPCRs) and PLC γ enzymes activated via growth factor receptors and immune cell receptors (Suh *et al.*, 2008; Gresset *et al.*, 2012; Kadamur and Ross, 2013). More recently, the role of small GTPases from Ras and Rho families in regulation of PLC β , PLC γ , and PLC ϵ enzymes has been also documented, extending the complexity of their regulatory networks (Harden and Sondek, 2006; Bunney and Katan, 2006).

Domain Organization and Structure of PLCs

As shown in Figure 1(b), PLC enzymes contain a pleckstrin homology (PH) domain (except for PLC ζ 1), four EF hands, a triose isomerase (TIM) barrel catalytic domain, and a C2 domain. The TIM barrel contains two regions of high sequence similarity, originally described as X and Y, corresponding to two halves of the TIM barrel structure. Between these two regions is a linker, the X–Y linker, which varies between PLC families. Each PLC family, except PLC δ and PLC ζ , has additional regulatory domains. PLC β and PLC η isoforms have C-terminal tails and PLC ϵ contains a Cdc25 domain and two Ras association (RA) domains. PLC γ isoforms contain a split PH domain (spPH), two Src homology 2 domains (nSH2 and cSH2), and a Src homology 3 (SH3) domain. The region containing these domains is known as the γ -specific array (γ SA) and is inserted between the two halves of the TIM barrel sequence, representing the most complex X–Y linker.

The crystal structure of PLC δ 1 (minus the PH domain) was the first structure of the catalytic region of a mammalian PLC enzyme to be solved (Essen *et al.*, 1996); this provided

structural insights into the PLC common core including inter-domain interactions and the mechanism of PIP₂ hydrolysis (Essen *et al.*, 1997). More recently, crystal structures of PLC β enzymes confirmed that inter-domain interactions between the TIM barrel and the EF hands and the TIM barrel and the C2 domain are conserved (Lyon *et al.*, 2011; Jezyk *et al.*, 2006). The only major difference is expected to be in the positioning of the PH domain. The PH domain of PLC δ 1 binds strongly to PI(4,5)P₂ and is attached to the rest of the enzyme by a flexible linker (Essen *et al.*, 1996) whereas the PH domain of some PLC β enzymes binds to small GTPases and is more integral to the enzyme structure (Jezyk *et al.*, 2006).

The progress has also been made in understanding the structural basis for activation of PLC enzymes, in particular for PLC β and PLC γ isoforms; the information covers complexes of PLC β with G α q and small GTPase Rac and of PLC γ with FGFR and Rac (Lyon *et al.*, 2011; Jezyk *et al.*, 2006; Waldo *et al.*, 2010; Bunney *et al.*, 2009; Bae *et al.*, 2009). Importantly, structure-based functional analysis revealed a general, auto-inhibitory mechanism that involves elements from the X–Y linker that in most PLC families contributes to occlude the active site in the TIM barrel; different regulatory interactions act to release this intra molecular inhibitory constraint as a step in a more complex activation process (Bunney and Katan, 2011).

Signaling Connectivity, Function, and Dysfunction

A number of different experimental approaches provided insights into physiologically important signaling connectivity for each PLC family. In addition, experimental evidence related to their dysfunction and links to disease highlighted their key regulatory roles. This information is summarized in Table 1.

PLC δ family

PLC δ isoforms 1, 3, and 4 comprise the PLC δ family. There is some evidence for signaling networks that involve PLC δ but they are not well defined. PLC δ 1 is the most studied of the PLC δ enzymes. Its activity is more sensitive to Ca²⁺ levels than most other PLCs and its PLC activity can be stimulated by Ca²⁺ levels within the physiological range (Allen *et al.*, 1997). It has been suggested, therefore, that PLC δ 1 could be stimulated downstream of the Ca²⁺ mobilized by activation of other PLCs or in the vicinity of calcium channels (Allen *et al.*, 1997; Thompson and Shuttleworth, 2011). The binding of the PLC δ 1 PH domain to PI(4,5)P₂ is also important for PLC δ 1 activity and can be competed out by IP₃ (Yagisawa *et al.*, 1998). Thus, changes in Ca²⁺, IP₃ or PI(4,5)P₂ could influence activity of PLC δ 1. Protein–protein interactions may also regulate PLC δ 1 activity. PLC δ 1 activation has been linked to two GTP binding proteins, G_h (also known as transglutaminase II), a high molecular weight GTP binding protein, and Ral, a member of the Ras family of small GTPases

Figure 1 Domain organization of the PLC enzymes. (a) PLC enzymes catalyzed hydrolysis $PI(4,5)P_2$ to IP_3 and DAG. (b) The basic structure of PLC enzymes consists of a PH domain (missing in $PLC\zeta 1$), four EF hands, a split TIM barrel catalytic domain and a C2 domain. The TIM barrel is formed from the X region and the Y region and the linker between the two is referred to as the X-Y linker. The PLC enzymes, except $PLC\delta$ and $PLC\zeta 1$, have additional regulatory regions. $PLC\beta$ and $PLC\eta$ have extended C-terminal regions. $PLC\gamma$ contains a spPH domain, two SH2 domains, and an SH3 domain within its X-Y linker. $PLC\epsilon 1$ has an N-terminal Cdc25 domain and two C-terminal RA domains. $PLC\epsilon 1$ also contains an insert in the Y region of the TIM barrel that is otherwise well conserved between PLC enzymes.

(Feng *et al.*, 1996; Sidhu *et al.*, 2005). However, none of these proposed interactions have been evaluated in biological contexts.

Some physiological roles of $PLC\delta$ enzymes can be suggested based on the phenotypes of knockout mice (Fukami *et al.*, 2008). For example, *Plcd1* knockout suggests that $PLC\delta 1$

Table 1 Expression, function and dysfunction of PLC enzymes

Human gene/protein	Expression pattern ^a	Phenotype of knockout mice	Dysfunction/disease
PLCD1/PLC δ 1	Most tissues	Hair loss (Nakamura <i>et al.</i> , 2005) Inflammation in the skin (Ichinohe <i>et al.</i> , 2007)	Possible tumor suppressor, down regulated in several cancers (Fu <i>et al.</i> , 2007; Hu <i>et al.</i> , 2009; Danielsen <i>et al.</i> , 2011)
PLCD3/PLC δ 3	Most tissues	No abnormality (Nakamura <i>et al.</i> , 2005)	Down regulated in some cancers (Danielsen <i>et al.</i> , 2011)
PLCD4/PLC δ 4	Higher in neuronal tissue	Male infertility (Fukami <i>et al.</i> , 2001)	
PLCB1/PLC β 1	Higher in neuronal tissue	Retarded growth, low viability, and epilepsy (Kim <i>et al.</i> , 1997)	
PLCB2/PLC β 2	High in hematopoietic cells	Defective leukocyte response to chemoattractants (Jiang <i>et al.</i> , 1997)	
PLCB3/PLC β 3	Most tissues	Macrophage hypersensitivity and reduced atherosclerosis (Wang <i>et al.</i> , 2008) Premature death, myeloproliferative disease, and lymphoma (Xiao <i>et al.</i> , 2009)	Possible tumor suppressor, reduced expression in some cancers, no identified mutations (Xiao <i>et al.</i> , 2009)
PLCB4/PLC β 4	Higher in neuronal tissue	Ataxia (Kim <i>et al.</i> , 1997)	
PLCG1/PLC γ 1	Most tissues High in T cells	Embryonic lethal, day E9 (Ji <i>et al.</i> , 1997)	Cancer promoting Increased expression in several cancers (Arteaga <i>et al.</i> , 1991; Noh <i>et al.</i> , 1994; Thomas <i>et al.</i> , 2003; Sala <i>et al.</i> , 2008) Gain-of-function mutations in some cancers (Behjati <i>et al.</i> , 2014; Vaque <i>et al.</i> , 2014) Gain-of-function function/hypomorphic mutations in immune disorders (Ombrello <i>et al.</i> , 2012; Zhou <i>et al.</i> , 2012)
PLCG2/PLC γ 2	High in hematopoietic cells	Decreased mature B cells, loss of function in other hematopoietic cells (Wang <i>et al.</i> , 2000a,b)	Mutations in nephrotic syndrome (Hinkes <i>et al.</i> , 2006)
PLCE1/PLC ϵ 1	Generally low expression	Heart defects (Tadano <i>et al.</i> , 2005; Wang <i>et al.</i> , 2005; Zhang <i>et al.</i> , 2013) Decreased tumor development due to decreased inflammation (Ikuta <i>et al.</i> , 2008; Li <i>et al.</i> , 2009) Increased tumor development due to changes in cancer cells (Martins <i>et al.</i> , 2014)	Possible tumor suppressor. Reduced expression in some cancers (Martins <i>et al.</i> , 2014; Sorli <i>et al.</i> , 2005; Danielsen <i>et al.</i> , 2011; Wang <i>et al.</i> , 2012). Single nucleotide polymorphisms associated with some cancers (Abnet <i>et al.</i> , 2010; Wang <i>et al.</i> , 2010)
PLCH1/PLC η 1	Neuronal		
PLCH2/PLC η 2	Neuronal	No global effects. Impact on development and maturation of retina (Kanemaru <i>et al.</i> , 2010)	
PLCZ1/PLC ζ 1	Testis/sperm		Reduced expression associated with infertility (Yoon <i>et al.</i> , 2008; Heytens <i>et al.</i> , 2009).

^aExpression patterns were determined from USCS Genome Bioinformatics (<http://genome.ucsc.edu>), Human Protein Atlas (<http://www.proteinatlas.org>), and Suh *et al.* (2008).

may influence inflammation in the skin (Ichinohe *et al.*, 2007) while PLC δ 4 may play a role in male fertility (Fukami *et al.*, 2001). *Plcd3* knockout mice did not have an abnormal phenotype but combined *Plcd1/Plcd3* knockouts die between days E11.5 and E13.5 due to defects in the placenta (Nakamura *et al.*, 2005).

PLC δ enzymes may play a role in cancer. It has been suggested that PLC δ 1 acts as a tumor suppressor in esophageal squamous cell carcinoma, gastric cancer, and colorectal cancer (Fu *et al.*, 2007; Hu *et al.*, 2009; Danielsen *et al.*, 2011). The chromosomal region that contains the *PLCD1* gene and several other candidate tumor suppressor genes is deleted in many cancers (Fu *et al.*, 2007; Hu *et al.*, 2009). PLC δ 1 was also found to be down regulated and its promoter methylated in a number of gastric cancer cell lines. Sixty-two percent of gastric cancer tumors showed *PLCD1* methylation, whereas no methylation was seen in any of the normal tissue controls (Hu *et al.*, 2009). PLC δ 1 protein expression was also decreased in

tumors. Expression of PLC δ 1 in gastric cancer cell lines decreased growth and migration and altered cell morphology. This effect is proposed to be mediated via PLC δ 1's effect on proteins that rearrange the cytoskeleton. In esophageal squamous cell carcinoma the tumor suppressive effects of PLC δ 1 were attributed to an effect on cell cycle progression through the G1-S checkpoint (Fu *et al.*, 2007). In colorectal cancer, reduced expression of PLC δ 1 was validated in biopsies and cell lines by quantitative analyses and found associated with *KRAS* mutations (Danielsen *et al.*, 2011). Promoter methylation analyses revealed that also in this cancer type, methylation of *PLCD1* can contribute to reduced expression.

PLC β family

PLC β isozymes (β 1- β 4) are well-documented targets downstream of GPCRs, activated by $G\alpha$ and $G\beta\gamma$ subunits of heterotrimeric G-proteins. Members of the Rho family GTPases, such as the Rac isoforms, also directly bind and activate PLC β ,

linking PLC β activity to GPCR-independent signaling cascades (Suh *et al.*, 2008; Gresset *et al.*, 2012; Kadamur and Ross, 2013).

Activation of PLC β by members of the Gq subfamily have prominent roles in cardiovascular function, chemotaxis, and neuronal signaling. Recent studies provided structural and mechanistic insights into PLC β activation by G α_q (Harden *et al.*, 2011; Lyon *et al.*, 2014). The main binding site of G α_q is the proximal site (near the C2 domain) of the C-terminal tail of PLC β (designated as proximal-CTD). A recently suggested mechanistic model implies that membrane recruitment on its own is not sufficient for the activation (Lyon *et al.*, 2014). Instead, it has been proposed that the binding of G α_q displaces the auto-inhibitory helix from the catalytic core, allosterically activating PLC β . Simultaneously, the distal CTD interacts with the membrane and with G α_q in a manner that helps the G α_q -catalytic core complex adopt a specific orientation with respect to the membrane surface. The resulting electrostatic repulsion between the membrane and acidic regions in the X-Y linker helps to open the active site, allowing binding of the PI(4,5)P₂ substrate. Thus, the distal CTD and the membrane could be acting as scaffolds that help to not only optimize the orientation of the G α_q -catalytic core complex, but also allosterically activate it. Interestingly, another region within PLC β subsequently accelerates GTP hydrolysis by of G α_q , leading to its inactivation and signal termination (Harden *et al.*, 2011).

As originally observed for PLC β 2, PLC β 1-3 are also activated by G $\beta\gamma$ dimers which is thought to be mediated by activation of Gi-coupled GPCR (Camps *et al.*, 1992). G $\beta\gamma$ dimers interact with PLC β 2 via its PH domain and in a chimeric protein the PLC β 2 PH domain is sufficient to make PLC δ 1 sensitive to stimulation by G $\beta\gamma$ (Wang *et al.*, 2000b).

Experiments *in vitro* and in COS-7 cells have shown that PLC β 2 is activated by the Rac and Cdc42 members of the Rho family of GTPases in a GTP dependent manner. PLC β 3 is less sensitive to activation in this way and PLC β 1 is Rac insensitive. Experiments using chimeras of PLC β 1 and PLC β 2 identified the N-terminal PH domain of PLC β 2 as a potential binding site for Rac (Illenberger *et al.*, 2003). The crystal structure of PLC β 2 and Rac1 further demonstrated that the PH domain is the only part of PLC β 2 that binds to the GTPase (Jezzyk *et al.*, 2006). It has been suggested that a major role of Rac binding could be translocation of PLC β 2 to the membrane.

Knockout mice have been generated for each of the four PLC β isozymes and suggest diverse physiological roles. *Plcb1*^{-/-} mice display retarded growth and low viability after birth (Kim *et al.*, 1997). The mice have recurrent epileptic seizures indicative of a role for PLC β 1 in the normal functioning of inhibitory neuronal circuitry. *Plcb4*^{-/-} mice also have a neuronal defect. They suffer from ataxia caused by retarded development of the cerebellum (Kim *et al.*, 1997). Further pharmacological experiments using the mice suggested that PLC β 1 is active downstream of muscarinic acetylcholine receptors in the cerebral cortex, hippocampus and cerebellum and PLC β 4 is downstream of both muscarinic acetylcholine receptors and metabotropic glutamate receptors in the cerebellum (Kim *et al.*, 1997). *Plcb2*^{-/-} mice show no effects at the systemic or cellular level. Neutrophils from the mice show decreased production of inositol phosphates in response to chemo-attractants (Jiang *et al.*, 1997). However, chemotaxis toward

these signals is increased. This suggests that chemotaxis is regulated by inputs from a number of pathways. *Plcb2*^{-/-} mice also show an enhanced response to bacterial or viral infection. *Plcb3* knockout results in mice with macrophages that are more sensitive to apoptosis (Wang *et al.*, 2008). When *Plcb3*^{-/-} mice are crossed with a model of atherosclerosis the mice lacking PLC β 3 have less atherosclerotic plaques.

More recently *Plcb3*^{-/-} mice have been reported to die prematurely, display symptoms of myeloproliferative disease and have various tumors (Xiao *et al.*, 2009). Based on this phenotype, PLC β 3 has been identified as a tumor suppressor (Xiao *et al.*, 2009). The phenotype is mediated by bone marrow cells and *Plcb3*^{-/-} cell populations enhanced for hematopoietic stem cells exhibit increased proliferation and decreased apoptosis. Interestingly, PLC β 3's tumor suppressive effect is mediated by its C-terminal tail and is independent of lipase activity. As yet no PLC β 3 point mutations have been identified in cancers but a small number of acute lymphocytic leukemia patients have a deletion of the chromosomal region that includes *PLCB3* and 11% of chronic lymphocytic leukemia samples studied had low PLC β 3 expression (Xiao *et al.*, 2009).

Recent studies of uveal melanomas suggest that PLC β could have an important role in this type of cancer without itself harboring mutations; the predominance of activating, somatic mutations in G α_q or G α_{11} in uveal melanomas results in constitutive activation of their downstream signaling responses (Van Raamsdonk *et al.*, 2009). In this context, PLC β could promote cancer formation rather than act as a tumor suppressor.

PLC γ family

PLC γ isoforms (PLC γ 1 and PLC γ 2) are activated downstream of receptor and non-receptor tyrosine kinases (Suh *et al.*, 2008; Gresset *et al.*, 2012; Kadamur and Ross, 2013). Action of non-receptor tyrosine kinases (from Src, Syk, and Tec families) has been best defined in the context of activation of immune cell (T cell, B cell, and Fc) receptors associated with multi-protein complexes. Ubiquitously expressed PLC γ 1 is activated downstream of growth factor stimulation, including stimulation by epidermal growth factor, platelet derived growth factor receptor, vascular endothelial growth factor and fibroblast growth factor (FGF). These growth factors regulate a number of cellular processes including proliferation, motility and cell survival; although PLC γ 1 could be involved in regulation of several of these processes, the importance of this PLC in cell motility has been best documented (Bunney and Katan, 2010). PLC γ 2, with highest expression in hematopoietic cells, is activated by immune cell receptors such as B cell and Fc receptors, however, T-cell receptor activation is linked to PLC γ 1. More recently it has been discovered that PLC γ 2 is activated by the small GTPase Rac, but as yet no activation of PLC γ 1 by GTPases has been identified (Piechulek *et al.*, 2005).

Phosphorylation of PLC γ by tyrosine kinases is important for its activation by these kinases. In both PLC γ 1 and PLC γ 2, the critical tyrosine residues (such as PLC γ 1 Y783 and PLC γ 2 Y759) are within a linker between cSH2 and SH3 domains. Recent structural and mechanistic studies focused on PLC γ 1 activation by tyrosine kinase receptors (Bae *et al.*, 2009; Bunney *et al.*, 2012). In a basal state, PLC γ is auto-inhibited by intramolecular interactions between the cSH2 domain and the

catalytic core. This auto-inhibitory interaction is out competed following phosphorylation within the linker region and by the subsequent binding of the phosphotyrosine to the cSH2 domain. In contrast to the cSH2 domain that appears to be mainly involved in intramolecular interactions, the nSH2 domain is the main determinant of recognition of specific binding sites on at least some growth factor receptors; this is best documented for FGF receptor (Bae *et al.*, 2009; Bunney *et al.*, 2012). Interestingly, activation of PLC γ 2 by Rac, that involves binding to the spPH domain within the γ SA, is independent of tyrosine phosphorylation and the mechanism of activation in this case remains unclear (Piechulek *et al.*, 2005; Bunney *et al.*, 2009).

Plcg1 knockout is embryonic lethal in mice at around embryonic day 9 (Ji *et al.*, 1997). At embryonic day 8.5–9.5 the *Plcg1*^{-/-} embryos are smaller than wild-type but no gross abnormalities are visible. Further analysis demonstrated that both erythropoiesis and vasculogenesis were significantly disrupted in these mice (Liao *et al.*, 2002). They lack expression of an adhesion molecule marker for endothelial cells; however the lack of blood vessels could be due to lack of angiogenesis or a defect in differentiation. In contrast, *Plcg2* knockout mice are viable but have significant defects in the immune system and platelets (Wang *et al.*, 2000a). FACS analysis shows that they have a shift toward immature B cell populations and a decrease in the mature B cell population. B cells from *Plcg2*^{-/-} mice do not mobilize Ca²⁺ in response to stimulation with anti-IgM but do respond normally to phorbol esters and ionomycin. Mast cells and natural killer cells also show decreased function following stimulation via the Fc ϵ R and Fc γ RII/II respectively. *Plcg2*^{-/-} mice experience increased hemorrhaging and their platelets do not aggregate or release TXA₂ or ATP in response to collagen. T cell function and signaling is normal in these mice. This shows that PLC γ 2 is nonredundant and mediates the effects of several immunoglobulin superfamily receptors (Wang *et al.*, 2000a).

The first evidence that PLC γ enzymes could be linked to complex disorders by incorporating gain-of-function or hypermorphic mutations came from a large-scale *N*-ethyl-*N*-nitrosourea mutagenesis screen. Among mouse strains with abnormal limbs due to severe inflammation two strains, abnormal limb 5 and 14 (Ali5 and Ali14), contained single point mutations in PLC γ 2 that resulted in gain-of-function (Yu *et al.*, 2005; Everett *et al.*, 2009; Abe *et al.*, 2011). Subsequently, genetic analyses of various dominantly inherited immune disorders in humans have revealed that mutations in the *PLCG2* gene are indeed causatively linked to two clinical syndromes designated as PLAID and APLAID syndrome (Ombrello *et al.*, 2012; Zhou *et al.*, 2012). PLAID patients have familial cold-induced urticaria that is caused by mast cell degranulation. They also have variable B cell immunodeficiency and a predisposition to developing skin granulomas and autoimmunity. Through linkage analysis and candidate gene sequencing of PLAID patients, it was found that they have large (4–8 kb) deletions in *PLCG2* that resulted in a cold sensitive activation of PLC γ 2 enzyme (Ombrello *et al.*, 2012). Another study identified a family with an autosomal dominant autoinflammatory disease of the eyes, skin and lungs linked to a point mutation in *PLCG2* (Zhou *et al.*, 2012). The disease that was observed in this family was designated

autoinflammatory PLAID or APLAID. The B cells of APLAID patients differed from those of patients with PLAID in that surface ligand-mediated cellular signaling was actually enhanced in these cells and there was no cold sensitivity.

Because PLC γ 1 is a common component downstream of many growth factor receptors mutated in cancer, it was assumed that it could contribute to tumor generation and progression as the key link to deregulation of processes such as cell motility. Initial studies of tumor samples also indicated that PLC γ 1 is overexpressed in human cancers including breast, colon and head and neck squamous cell carcinomas (Arteaga *et al.*, 1991; Noh *et al.*, 1994; Thomas *et al.*, 2003). An increase in PLC γ 1 phosphorylation in tumor samples was also identified (Thomas *et al.*, 2003). Furthermore, increased levels of PLC γ 1 expression have been detected in lymph node metastases compared to primary tumors from breast cancer patients (Sala *et al.*, 2008). However, it was only recently that gain-of-function mutations in PLC γ 1 have been identified in tumor samples, providing evidence for its role as an oncogene. Two independent studies identified recurrent mutations in *PLCG1* in about 10% of angiosarcomas, characterized by aberrant angiogenesis (Behjati *et al.*, 2014), and in about 20% of cutaneous T-cell lymphomas (Vaque *et al.*, 2014); in both types of these relatively rare cancers, aggressive forms lack effective treatment.

It is also possible to interpret various gain-of-function mutations in PLC γ enzymes within the structural framework for PLC γ activation and auto-inhibition (Bunney *et al.*, 2012). It appears that deletions and point mutations, found in immune disorders and cancer, affect regions within the auto-inhibitory surface either within the γ SA (in particular cSH2 domain) or in the vicinity of the active site, resulting in the constitutive or enhanced activation.

PLC ϵ 1

PLC ϵ 1, the largest PLC enzyme, is downstream of both GPCRs and receptor tyrosine kinases by virtue of its ability to be regulated by small GTPases from Ras and Rho families (Bunney and Katan, 2006; Harden and Sodek, 2006; Smrcka *et al.*, 2012). However, PLC ϵ 1 appears to mediate more-sustained phosphoinositide hydrolysis compared to the more receptor-proximal PLC β and PLC γ enzymes; PLC ϵ 1 does so through its regulation by a distinct set of GPCRs and at least some receptor tyrosine kinases (Smrcka *et al.*, 2012).

PLC ϵ 1 activation by classical members of the Ras family (H-Ras, K-Ras, and N-Ras) is through binding to the RA2 domain (Bunney *et al.*, 2006). The affinity of Ras for the PLC ϵ 1 RA2 domain is similar to its affinity for PI3-kinases and RalGDS, however it is lower than its affinity for Raf-1. One of the roles of Ras binding appears to be translocation of PLC ϵ 1 to the membrane. Adding a membrane-targeting tag to PLC ϵ 1 removes the requirement for the RA2 domain in activation. However, Ras binding may also contribute to conformational change. PLC ϵ 1 is also activated by Rap1, Rap2, and R-Ras. *In vitro* the binding of these GTPases to the RA2 domain has 10-fold less affinity than the binding of classical Ras proteins but in cells other factors may contribute to activation (Bunney *et al.*, 2006). Activation by Rho GTPases is independent of the RA2 domain and may involve a unique insert in the Y-box.

PLC ϵ 1 also contains a region in its N-terminus that has homology with the Cdc25 domain found in Ras family guanine exchange factors (GEFs) including SOS and Epac. The Cdc25 domain is the catalytic domain of these GEFs and catalyzes the conversion of GTPases from their GDP to GTP bound form. In their GTP bound form they are able to bind to and influence their effectors. The presence of a Cdc25 domain in PLC ϵ 1 suggests that PLC ϵ 1 could regulate the activity of Ras family GTPases as well as being activated by them. One study has suggested that this domain has GEF activity for H-Ras as H-Ras-GTP levels increased when PLC ϵ 1b was expressed and this effect was independent of lipase activity (Lopez *et al.*, 2001). A separate study of the PLC ϵ 1a splice variant looked for GEF activity toward H-Ras, M-Ras, Rap1, Rap2, RalA, Rit, Rin, and Rheb. This study demonstrated that the GEF activity was selective for Rap1 (Jin *et al.*, 2001). The role of the Cdc25 domain is, therefore, still unclear and it remains possible that the domain has no direct GEF activity. If the domain is active, the regulation of its activity may involve the other domains of PLC ϵ 1.

PLC ϵ 1 transgenic mice were first generated by in-frame disruption of the catalytic domain (PLC ϵ 1 Δ x/ Δ x). These mice were found to have heart valve defects, although the mice were viable (Tadano *et al.*, 2005). Another study of PLC ϵ 1 mice disrupted the *Plce1* gene in a way that resulted in a near complete knockout (PLC ϵ 1 $^{-/-}$) (Wang *et al.*, 2005). This study detected different heart defects, pointing to a role for PLC ϵ 1 in GPCR-mediated hypertrophic growth of cardiomyocytes. Cardiac myocytes from these mice showed decreased Ca $^{2+}$ signaling in response to β -adrenergic stimulation. Subsequently, it was shown that the hypertrophy of neonatal rat ventricular myocytes driven by ET-1, norepinephrine, or isoproterenol was inhibited by small interfering RNA-mediated knockdown of PLC ϵ 1 (Zhang *et al.*, 2011). Furthermore, it was shown that PLC ϵ scaffolds to muscle-specific A kinase-anchoring protein at the nuclear envelope, and disruption of this scaffolding interaction prevents development of agonist-induced hypertrophy (Zhang *et al.*, 2011). The important insight into the mechanistic role of PLC ϵ 1 in cardiac function and failure was recently obtained from targeted deletion of *Plce1* specifically in cardiac myocytes in mice after development; these mice are protected from pressure-overload-induced hypertrophy, clearly identifying the *Plce1* gene as critical for the development of heart failure (Zhang *et al.*, 2013).

Findings that PLC ϵ 1 can directly bind and be activated by Ras GTPases that are frequently mutated in several cancer types, prompted search for possible links between the Ras oncogene and PLC ϵ 1 in the context of cancer. Notably, PLC ϵ 1 transgenic mice were tested in different cancer models. Initial studies using PLC ϵ 1 Δ x/ Δ x mice indicated that PLC ϵ 1 may play a role in tumorigenesis as they show decreased skin tumor formation in a two-stage model of skin chemical carcinogenesis (Bai *et al.*, 2004). Later studies suggested that PLC ϵ 1 was not involved in proliferation of keratinocytes driven by the oncogenic Ras but was instead involved in TPA induced inflammation (Ikuta *et al.*, 2008). In cultures of dermal fibroblasts TPA induces PLC ϵ 1 activity leading to the production of interleukin-1 α , a proinflammatory molecule. This suggests that PLC ϵ 1's role in cancer may be in the cells surrounding the tumor rather than the tumor itself. When

PLC ϵ 1 Δ x/ Δ x background was combined with a genetic mouse model for human colorectal tumorigenesis, also dependent on immune responses, the mice had resistance to spontaneous tumorigenesis (Li *et al.*, 2009). In contrast to these observations, PLC ϵ 1 $^{-/-}$ mice exhibited increased susceptibility to tumor formation in the two-stage skin carcinogenesis protocol revealing a tumor suppressor function for this PLC in cancer cells. Although significant differences were not seen in the *LSL-KrasG12D* non small cell lung carcinoma model, down-regulation of PLC ϵ was found in animal tumors and in cellular systems following expression of the oncogenic Ras (Martins *et al.*, 2014). Furthermore, tumor suppressor role of PLC ϵ 1 observed in these mouse models is consistent with observations of marked down-regulation in several types of human tumors, including lung and colorectal cancer, and the inhibitory effects of PLC ϵ 1 expression on cell growth (Martins *et al.*, 2014; Sorli *et al.*, 2005; Danielsen *et al.*, 2011; Wang *et al.*, 2012). Thus, it appears that PLC ϵ 1 could have multiple and context dependent roles in tumor environment and cancer cells themselves.

A link between PLC ϵ 1 and a development of human tumors was also suggested by genome-wide association studies; the studies identified *PLCE1* single nucleotide polymorphisms (SNPs) associated with esophageal squamous cell carcinoma (ESCC) (Abnet *et al.*, 2010; Wang *et al.*, 2010). One of the studies also found that the same *PLCE1* SNPs associated with ESCC were also associated with gastric adenocarcinoma (Abnet *et al.*, 2010). Whether these alterations associated with the *PLCE1* SNPs alter *PLCE1* function or expression is unknown and it remains unclear whether such alterations are causal or merely correlated with the ESCC or gastric adenocarcinoma.

Mutations in PLC ϵ 1 have been identified in patients with nephrotic syndrome, a kidney disease (Hinkes *et al.*, 2006). Seven homozygous mutations have been identified, six truncation mutations and one missense mutation. Patients with PLC ϵ mutations have impaired glomerular development, thus it has been suggested that PLC ϵ signaling may be involved in this process.

PLC η family

PLC η 1 and PLC η 2 were the most recently identified PLC isoforms (Katan, 2005). There are three splice variants of PLC η 1 and five splice variants of PLC η 2. These variants differ in their C-terminal tails (Hwang *et al.*, 2005; Zhou *et al.*, 2005). The PLC η isoforms are expressed in neuron enriched regions and are abundant in the brain (Stewart *et al.*, 2007). In COS-7 cells, co-expression of PLC η 2 with G β $_1\gamma$ $_2$ resulted in an increase in PLC activity (Zhou *et al.*, 2005). No other G $\beta\gamma$ dimer produced activation and PLC η 1 was not activated in this way. The activation did not require the C-terminal tail region of the enzyme. Activation was also seen in reconstitution assays using almost pure protein suggesting that the activation was due to a direct interaction.

PLC η 2 knockout mice are viable and further analysis suggested the role of PLC η 2 in development and maturation of retina where this PLC is highly expressed (Kanemaru *et al.*, 2010).

PLC ζ 1

PLC ζ 1 is the smallest mammalian PLC enzyme and is the only one not to contain a PH domain. It is around 100 times more

sensitive to Ca^{2+} than $\text{PLC}\delta 1$ and is activated at levels of Ca^{2+} found in resting cells (Nomikos *et al.*, 2005). This testis-specific PLC is expressed in sperm and is believed to be the sperm factor required to induce Ca^{2+} oscillations in fertilized eggs (Amdani *et al.*, 2013, Kashir *et al.*, 2014). These oscillations are required for egg activation and completion of meiosis. $\text{PLC}\zeta 1$ may be inactivated in some way in sperm, possibly by its localization, and then activated by resting Ca^{2+} levels in the egg following fertilization. At fertilization, the sperm initiates development by causing a series of oscillations in concentrations of calcium Ca^{2+} within the egg. $\text{PLC}\zeta 1$ mimics the sperm at fertilization, causing the same pattern of Ca^{2+} release as seen at fertilization.

A number of reports from the clinic support the link between defects in human $\text{PLC}\zeta 1$ and the inability of sperm to cause egg activation. Sperm of some infertile men are unable to induce Ca^{2+} oscillations upon microinjection into mouse oocytes and such patients exhibited reduced/absent levels of $\text{PLC}\zeta 1$ (Yoon *et al.*, 2008, Heytens *et al.*, 2009). The failure to activate egg can be in some instances treated by using artificial egg activation methods, such as applying Ca^{2+} ionophores. Indeed, high fertilization rates were achieved with patients whose sperm were deficient in $\text{PLC}\zeta 1$ when a Ca^{2+} ionophore was used to artificially activate eggs (Taylor *et al.*, 2010). It is hoped that the use of purified $\text{PLC}\zeta 1$ can provide a better option for this type of artificial fertilization, bypassing possible side effects of Ca^{2+} ionophores.

Glossary

Apoptosis/programmed cell death Death of cells by mechanisms that are carefully controlled: a positive way to use the calcium signal.

Calcium pathologies Uncontrolled activation of hydrolytic enzymes (proteases, phospholipases, and nucleases) by excess calcium.

Calcium signaling Transfer of information by calcium to intracellular protein targets.

Calmodulin A protein that binds calcium to decode its message and to transfer it to protein targets.

Protein kinases Enzymes that hydrolyze ATP to phosphorylate proteins.

Calcium, the third most abundant metal in nature, is present in living organisms in salts of various compositions. In animals, calcium phosphate is the major salt of bones and teeth, which contain more than 99% of the total Ca^{2+} of the body. In man, the concentration of Ca^{2+} in the body fluids and the extracellular spaces oscillates between 2.1 and 2.6 mM (Woodhead, 1982). The concentration of Ca^{2+} in the blood and the extracellular spaces, and the equilibrium between its free (ionized), and bound and/or salt-precipitated forms, is regulated by three hormones, parathyroid hormone, calcitonin, and Vitamin D. They act on the three systems that preside over the dynamic equilibrium of Ca^{2+} in the body: the intestine, the kidney, and the bone compartment. About half of the blood Ca^{2+} is free, the other half is complexed to organic or inorganic compounds. Total Ca^{2+} is in the millimolar concentration range also inside cells, however, its free concentration in the cytosol, where most of the targets of its signaling function reside, is but a negligible fraction of the total: normally, it is maintained in the 100–300 nM level, which is the level in which the regulation of the signaling function of Ca^{2+} occurs. The balance between free and bound Ca^{2+} in the cytosol is a complex process in which the binding of the metal to inorganic ligands and small molecular weight organic molecules has a role (Brini *et al.*, 2013b). However, the complexation by these ligands cannot lower the concentration of free Ca^{2+} to the nanomolar level. This low concentration is achieved thanks to the intervention of specific proteins that coordinate Ca^{2+} to complex sites that have the appropriate affinity and specificity for it. These proteins exploit the peculiar coordination chemistry of Ca^{2+} , which determines the ease with which it can be ligated to the sites of irregular geometry their structures offer. Ca^{2+} -ligation usually occurs via carboxylates (mono- or bidentate) or neutral oxygen donors since the calcium ion prefers oxygen as donor groups of ligands. In proteins, calcium is generally bound by seven oxygen atoms in a conformation which is best represented by a pentagonal bipyramid.

The advantage of Ca^{2+} in the ligation process becomes clear on comparing it, for instance, to the other Group 2 metal, Mg^{2+} . The range of distances Mg^{2+} can accept from the coordinating oxygens of the binding site is much more restricted than in the case of Ca^{2+} : Mg^{2+} would thus demand perfectly

octahedral-binding sites, which are obviously unlikely to be found in proteins, whereas Ca^{2+} easily accepts the sites of more irregular geometry that one may expect in their structures (Carafoli and Penniston, 1985). Proteins endowed with the ability to specifically bind Ca^{2+} may be divided in two large families: those that transport it across membranes and those that reversibly complex it in the cytosol and in the lumen of the organelles.

The EF-Hand Calcium-Binding Principle

The intracellular level of free Ca^{2+} in eukaryotic cells can transiently increase above the 100–300 nM concentration level in response to extracellular signals. To function as a carrier of messages the Ca^{2+} -signal must be processed by Ca^{2+} -binding proteins. At variance with the extracellular proteins that bind Ca^{2+} with low affinity, intracellular proteins bind it with high affinity to a number of structural motifs. The most common (and most important) is a sequential arrangement of about 30 amino acids that ligate Ca^{2+} in a loop flanked by two helical segments. This helix-loop-helix Ca^{2+} -binding motif, which is known as the 'EF-hand' was introduced by Kretsinger (Kretsinger and Nockolds, 1973) from the 3D structure of parvalbumin. It revealed six α -helices, designated A through F: the spatial arrangement of the fifth (E) and sixth (F) α -helix enclosing the calcium-binding loop resemble a human hand, the 'EF-Hand,' as shown in Figure 1. After the original parvalbumin work, the 'EF-hand' motif was discovered in numerous other proteins as a highly conserved structural Ca^{2+} -binding arrangement in intracellular proteins that mediate cellular responses. The family of proteins which contain EF-Hand motifs, presently numbers more than 800 members, and is steadily increasing, (Kawasaki *et al.*, 1998). Calmodulin (CaM), troponin C, recoverin, and S100 are some of the important proteins of the superfamily.

All EF-hand domains show a pentagonal-bipyramidal coordination pattern of Ca^{2+} in the loop flanked by two helices approximately perpendicular to each other. The residues forming the ligands to Ca^{2+} are highly conserved within a contiguous sequence of 12 residues spanning the loop and the beginning of the second helix.

Figure 1 The EF-hand as proposed by Kretsinger based on the crystal structure of parvalbumin can be represented by the forefinger (helix E) and the thumb (helix F), both enclosing the Ca^{2+} -binding loop, represented by the bent middle finger. Adapted from Kretsinger, R.H., 1975. Hypothesis: Calcium modulated proteins contain EF hands. In: Carafoli, E., Clementi, F., Drabikowsky, W., Margreth, A. (Eds.), *Calcium Transport in Contraction and Secretion*. Amsterdam: Elsevier, pp. 469–478.

The Ca^{2+} -binding domains usually occur in pairs stabilized by hydrogen-bond bridges between the central residues of adjacent loops, which form a minimal antiparallel beta-sheet. The pair-forming Ca^{2+} -binding domains enhance the Ca^{2+} -affinity and the cooperativity of binding. CaM and troponin C, the Ca^{2+} -binding protein of muscles, contain four such Ca^{2+} -binding sites. Both proteins display Ca^{2+} -binding characteristics compatible with a 'pair of pairs'-model of EF-hands, i.e., the two globular at the N- and C-terminal domains of the protein each contain a pair of EF-hands, the two globular domains being connected by a long helix that confers a dumbbell-shaped appearance to the protein. However, the central portion of the helix connecting the terminal lobes acts as a flexible hinge, which plays an important role in the interaction of the proteins with targets as it permits a broad range of spacing between the hydrophobic anchor residues in the globular lobes. Upon binding of Ca^{2+} , and subsequent interaction with targets, a conformational change of the protein occurs that transforms its extended, dumbbell-shaped structure into a more compact hairpin-like form that wraps itself around the target (Yap *et al.*, 1999).

A number of cellular Ca^{2+} -binding proteins are not structurally organized on the EF-hand principle. Among them are the Ca^{2+} -buffering proteins of the endoplasmic reticulum calreticulin and calsequestrin, phospholipase A2, protein kinase C, membrane-intrinsic proteins such as the annexins, and proteins containing the structural motif defined as the C_2 domain. The large family of annexins is of particular interest. Its members bind to membranes containing negatively charged phospholipids in a Ca^{2+} -dependent manner and

have a role in a number of important cellular functions, such as membrane fusion, signal transduction, and phospholipase modulation (Gerke *et al.*, 2005). An important member of the C_2 domain containing proteins is synaptotagmin, the Ca^{2+} -sensor required for membrane fusion during endo- or exocytosis.

CaM

CaM is the most conserved protein of the EF-hand superfamily, and is ubiquitously expressed in eukaryotic organisms (Klee and Vanaman, 1982). The sequences of CaMs of all vertebrates are 100% identical. In fact, CaM is ranked among the most conserved proteins known so far, together with proteins like histones, actin, or ubiquitin (Copley *et al.*, 1999). Human CaM is encoded by three nonallelic genes (Fischer *et al.*, 1988). The three genes encode an identical protein, but the coding sequences differ substantially.

CaM is the modulator that mediates the Ca^{2+} signal to most targets in eukaryotic cells. It regulates numerous fundamental cellular activities, among them glycogen metabolism, intracellular motility, Ca^{2+} -transport across membranes, cyclic nucleotide metabolism, protein phosphorylation and dephosphorylation, cell cycle progression, and gene expression. It controls these processes by interacting directly with a number of key enzymes such as the Ca^{2+} ATPase (PMCA pump) of the plasma membrane, different kinases, and the protein phosphatase calcineurin (CaN). It can regulate proteins with opposite functions, like adenylate cyclases and cyclic nucleotide phosphodiesterases. In addition to interacting reversibly with targets, in some cases CaM acts as a permanent subunit of enzymes, for example, phosphorylase kinase (Shenolikar *et al.*, 1979) and CaM-dependent kinases of plants (Roberts and Harmon, 1992). CaM is a monomer of approximate molecular weight 17 000, which is mainly located in the cytosol. However, it can be translocated to the nucleus (Pruschy *et al.*, 1994) where it plays a role in gene transcription and regulation of gene expression.

The structure of CaM has been solved for both the Ca^{2+} -saturated (Babu *et al.*, 1985) and the Ca^{2+} -free form (Kuboniva *et al.*, 1995; Zhang *et al.*, 1995). As mentioned, upon binding of Ca^{2+} , CaM alters its conformation exposing hydrophobic patches on its surface (LaPorte *et al.*, 1980; Krebs *et al.*, 1984; Figure 2). This confers to the protein the ability to interact with targets. A defined consensus sequence for CaM-binding sites in target proteins does not exist, but a number of characteristic features have been described such as high helix propensity, net positive charge, and two hydrophobic anchor residues spaced by a certain number of amino acids (James *et al.*, 1995). A number of structures of Ca^{2+} -loaded CaM complexed with binding peptides corresponding to the binding domains of protein targets have been solved (e.g., see Elshorst *et al.*, 1999; Juranic *et al.*, 2010; for a detailed review see Villarroel *et al.*, 2014). These studies have provided evidence for the general conclusion briefly mentioned above that the binding of target peptides induces a large conformational change of Ca^{2+} saturated CaM, which bends from the extended dumbbell shape into a more globular structure in which the two halves of CaM wrap around the target peptide

(Ikura *et al.*, 1992; Meador *et al.*, 1992; Figure 3). High-resolution structures of CaM complexed to entire protein targets exist only for two calmodulin-dependent kinases, CaM kinase II and the death-associated protein kinase (DAPK) (Rellos *et al.*, 2010; De Diego *et al.*, 2010, see below). The general molecular pattern of the molecular interaction of CaM with target domains that has emerged from these studies is supported by experiments using small-angle X-ray diffraction and neutron scattering. In these experiments, CaM complexed to intact myosin light chain kinase (MLCK) CaM undergoes a conformational collapse identical to that observed with the peptide corresponding to the CaM-binding domain of MLCK (Krueger *et al.*, 1997).

In addition to the CaM-binding motif in which hydrophobic residues spaced by a certain number of amino acids bind to hydrophobic pockets in CaM, a different motif for

CaM binding has been characterized more recently, the so-called IQ-motif, to which CaM can bind even in the absence of Ca^{2+} . This motif contains a conserved isoleucine next to a conserved glutamine and, C-terminal to it, at least one basic residue, normally arginine, with a number of residues in between (usually 3 or 4). The consensus sequence is thus $\text{IQX}_{(3\text{or}4)}\text{RGX}_{(3\text{or}4)}\text{R}$. A prominent example of this motif is found in the voltage-dependent calcium channel, which contains an IQ-motif in the C-terminal portion of its α subunit (see below). X-ray work has shown that CaM binds to a binding peptide that includes the IQ-motif (Fallon *et al.*, 2005).

Regulation of Ca^{2+} by Proteins that Mediate Its Membrane Transport

Ca^{2+} Channels

Ca^{2+} enters the cytosol from the external spaces, and the lumen of the intracellular organelles, through carefully controlled proteinaceous channels (see Brini *et al.*, 2013a for a recent review). Those in the plasma membrane have been historically divided in three major groups, depending on the mechanism by which their operation is regulated: (1) the voltage gated channels (VOCs), which transduce the changes in membrane potential into intracellular Ca^{2+} transients, (2) the receptor-operated channels (ROCs), which are activated by extracellular ligands, and (3) the store-operated channels (SOCs), which are activated by the emptying of the cellular Ca^{2+} stores (Figure 4). The VOCs are complexes of five subunits: the α 1 subunit, which contains the channel proper, is organized in four repeated modules of six transmembrane domains, the fourth of which contains the voltage sensor that gates the channel. The most important ROCs are those activated by the brain excitatory transmitter L-glutamate, which also interacts with a canonical seven-transmembrane receptor

Figure 2 Ca^{2+} -free (apo) calmodulin (1DMO.pdb). The blue ribbons show secondary structural elements of CaM, the green sticks show different methionine residues important for the interaction with targets. The overall structure shows the dumbbell shape typical for target-free CaM. Reproduced from Stathopoulos, P.B., Ames, J.B., Ikura, M., 2007. Structural aspects of calcium binding proteins and their interactions with targets. In: Krebs, J., Michalak, M. (Eds.), Calcium: A Matter of Life or Death. Amsterdam: Elsevier, pp. 95–123.

Figure 3 Surface representation of Ca^{2+} -bound CaM, and of its different binding modes to peptides. The N-terminal halves of CaM are in orange, the C-terminal halves are in red, the different peptides bound to CaM are in blue. The orientation of the C-terminal half of CaM is the same for all three structures. (a) Crystal structure of Ca^{2+} -bound calmodulin. (b) Solution structure of Ca^{2+} -CaM bound to a peptide (C20W) representing the N-terminal portion of the CaM-binding domain of the plasma membrane Ca^{2+} pump (lacking the C-terminal hydrophobic anchor residue): the peptide only binds to the C-terminal half of CaM. (c) Solution structure of the complex of Ca^{2+} -CaM with the CaM-binding domain of MLCK (M13) demonstrating that CaM changes to a compact globular conformation in which its N- and C-terminal halves wrap around M13. Reproduced from Elshorst, B., Hennig, M., Försterling, H., *et al.*, 1999. NMR solution structure of a complex of calmodulin with a binding peptide of the Ca^{2+} pump. Biochemistry 38, 12320–12332.

Figure 4 Schematic representation of the Ca^{2+} transporters and channels in the plasma membrane and the intracellular organelles. Most of the systems shown in the figure are mentioned in the text. G-protein-coupled receptor (GPCR) indicates the seven transmembrane domains receptors linked to Gq proteins that liberate InsP_3 in response to specific agonists by acting on the phospholipase C that hydrolyzes phosphatidyl-inositol-bis-phosphate (PIP₂). DAG is diacyl-glycerol. Transient receptor potentials (TRPs) are channels that can also mediate Ca^{2+} intake. The cartoon does not show the acidic organelles that have also been claimed to be a Ca^{2+} store. Modified from Brini, M., Ottolini, D., Cali, T., 2013a. Intracellular calcium homeostasis and signaling, In: Banci, L. (Ed.), *Metallomics and the Cell, Metal Ions in Life Sciences*, vol. 12. Dordrecht: Springer Science + Business Media, pp. 119–168.

coupled to G-proteins. The L-glutamate activated channels are divided into three groups based on the activity of specific agonists. They are multisubunit, relatively nonselective cation channels, in which the subunits contribute four transmembrane domains that form the cationic channel (however, transmembrane domain 2 does not cross the full width of the membrane). The SOCs are channels that are operated by the interplay of transmembrane Ca^{2+} -binding proteins in the endoplasmic reticulum that sense the level of Ca^{2+} filling within its lumen (STIM proteins). The STIM proteins communicate physically with a plasma membrane counterpart, which is the Ca^{2+} forming channel (the ORAI proteins). The ORAI protein family is composed of three subunits: ORAI 1 contains four transmembrane that form the pore (Hou *et al.*, 2012). When depletion of the Ca^{2+} store occurs, STIM proteins undergo a conformational change that redistributes them to discrete plasma membrane districts where ORAI proteins also redistribute (see Figure 4). Their interaction allows the opening of the ORAI1 channel.

Two channel types mediate the efflux of Ca^{2+} from the endo(sarco)plasmic reticulum and the Golgi system, which are the main intracellular Ca^{2+} stores: the inositol 1,4,5-trisphosphate (InsP_3) operated receptor/channel, which is expressed ubiquitously in tissues, and the ryanodine receptor/channel

(RyR), which has tissue restricted expression. Both are very large tetrameric molecules, which span the membrane with six hydrophobic helices. The very large portion of the molecules that protrudes into the cytosol contains binding sites for numerous regulators of the channel activity. One of them is Ca^{2+} , which acts either as a positive or a negative agonist of the InsP_3 R depending on its concentration. It activates the opening of the RyR in heart (triggering the Ca^{2+} -induced Ca^{2+} release mechanism, CICR), but not in skeletal muscles, where the activation of the channel requires the physical interaction between the plasma membrane VOCs and the RyR (the electromechanical coupling). Both the InsP_3 R and the RyRs are products of multigene families: three variants of each have been described, having tissue specific expression. Recent X-ray work has clarified many structural aspects of the function and regulation of the InsP_3 R, and the full 3D structure of the RyR has been solved by cryo-EM work (see for instance Zalk *et al.*, 2015).

Ca^{2+} Transporters

The ejection of Ca^{2+} from the cytosol to the extracellular space and from the lumen of intracellular organelles is performed by

ATPases (pumps) and $\text{Na}^+/\text{Ca}^{2+}$ -exchangers (Figure 4). Animal cells express Ca^{2+} pumps in the plasma membrane (PMCA pumps), in the endo(sarco)plasmic reticulum (SERCA pumps), and in the Golgi vesicles (SPCA pumps) (other Ca^{2+} pumps are expressed in plant cells and in lower eukaryotes). All these pumps belong to the superfamily of P-type ATPases, which are characterized by the temporary conservation of the energy of ATP in the form of an aspartyl-phosphate during the reaction cycle. They are organized in the membrane with 10 transmembrane domains, the larger portion of the structure protruding into the cytosol. A distinctive property of the PMCA pump is the presence of a long cytosolic C-terminal tail that houses important regulatory sites. The molecular details of the path of Ca^{2+} across the molecule of P-type pumps have been clarified by a number of X-ray studies on the SERCA pump (Toyoshima *et al.*, 2000). They have then been used as templates to model the molecular path for Ca^{2+} in the other two pumps. All three Ca^{2+} pumps are the products of multigene families, the isoforms having different tissue distribution and functional properties (mainly pertaining to their regulation) (Brini and Carafoli, 2009). Quantitatively, the SERCA pump has the most important role in the regulation of the homeostasis of Ca^{2+} in the cytosol, and thus in the overall control of the activity of the targets of Ca^{2+} signaling, whereas the SPCA pump may be predominant in special cell types, for example, the keratinocytes. The Ca^{2+} ejection activity of the PMCA pump probably does not have a significant role in the regulation of the homeostasis of Ca^{2+} in the bulk cytosol, considering the much greater amounts of the SERCA pump existing in most cells and, especially, the presence of the much more powerful $\text{Na}^+/\text{Ca}^{2+}$ -exchanger in the plasma membrane (see below). The concept has thus recently emerged that the main role of the PMCA pump would be that of regulating the concentration of Ca^{2+} in selected microdomains around its cytosolic protruding portion, which may contain important Ca^{2+} sensitive enzymes (Mohamed *et al.*, 2011).

The PMCA pump is of particular interest from another angle as well, as it is a target of the regulation by CaM, and is thus a striking example of the autoregulatory property of the Ca^{2+} signal. The activation of the PMCA pump by CaM has an additional point of interest: as the pump becomes activated, the concentration of Ca^{2+} in the microambient surrounding its cytosolic portion decreases, causing the detachment of CaM from its binding site in the cytosolic C-terminal tail of the pump. The detachment may be incomplete, as CaM may still remain partially bound to the pump with its C-terminal moiety, but the activity of the pump would necessarily decrease to a fraction of maximal. The lower activity would increase the concentration of Ca^{2+} in the pump microambient, promoting the full re-association of CaM with the pump, effectively reinitiating the activation/deactivation cycle. In essence, then, the activation of the PMCA pump by CaM cannot be permanent, but is bound to have oscillatory character. One last aspect of the function of the PMCA pump in the local regulation of the cytosolic Ca^{2+} is of interest: its isoforms have recently been found to regulate the Ca^{2+} transients produced by the triggering of the SOC channels (see above) in ways that differ depending on the peculiarities of their functional activity (Pászty *et al.*, 2015).

The plasma membrane of most animal cells contains a system that ejects Ca^{2+} in exchange for Na^+ (NCX). The

exchanger has lower affinity for Ca^{2+} than the Ca^{2+} pumps, and is particularly active in cells of excitable tissues like the heart and the nervous system. It has a much larger transport capacity than its companion plasma membrane Ca^{2+} transporter, the PMCA pump (Carafoli *et al.*, 2001), and thus efficiently restores the cytosolic Ca^{2+} concentration to resting values after the large increases physiologically occurring in cells like the neurons or the cardiomyocytes. It operates electrogenically, exchanging three Na^+ per one Ca^{2+} using the energy of the trans-plasma membrane electrochemical Na^+ gradient to eject Ca^{2+} ; however, the direction of the exchanger can be reversed by changes in the concentrations of the transported ions; if the concentration of Na^+ in the cytosol increases abnormally, as for example, in cardiomyocytes exposed to inhibitors of the plasma membrane Na^+/K^+ -ATPase like digitalis, the NCX will promote the influx of Ca^{2+} . The NCX is the product of a multigene family, the three basic isoforms having different tissue distribution and regulatory properties. All NCXs are organized in the membrane with nine transmembrane domains separated in two parts by a 500 amino acid cytosolic loop (Nicoll *et al.*, 2002). Partial 3D structures of the mammalian NCX have been published (Nicoll *et al.*, 2006; Hilge *et al.*, 2006), and the full structure of a prokaryotic exchanger has also been published (Liao *et al.*, 2012).

A phylogenetically ancestral branch of the $\text{Na}^+/\text{Ca}^{2+}$ exchanger superfamily also exchanges Li^+ , which is not accepted by the canonical NCXs. It has recently been identified (Palty *et al.*, 2010) as the variant of the $\text{Na}^+/\text{Ca}^{2+}$ exchanger that mediates the release of Ca^{2+} from the mitochondria (Carafoli *et al.*, 1974), which are now, after a long period of oblivion, have now become very important in the regulation of the cytosolic homeostasis of Ca^{2+} . Mitochondria had been shown to take up Ca^{2+} in the 1960s (De Luca *et al.*, 1961; Vasington and Murphy, 1962). However, their low Ca^{2+} affinity had negated their role in the regulation of cytosolic Ca^{2+} , relegating their Ca^{2+} transporting ability to a long period of obscurity (Carafoli, 2010). In the 1990s, it was discovered that the close proximity of endoplasmic reticulum to mitochondria generated local Ca^{2+} pools of sufficient Ca^{2+} concentration to activate their low affinity uptake system (Rizzuto *et al.*, 1992). Thus, mitochondria are thus now considered very important in the regulation of the cytosolic homeostasis of Ca^{2+} . Their uptake system is a channel uniporter (MCU) that operates in conjunction with one or more superficial components (MICU1) that may 'sense' Ca^{2+} to pass it out to the transmembrane MCU (De Stefani *et al.*, 2011; Baughman *et al.*, 2011; Figure 5).

CaM Targets

Calmodulin-Dependent Protein Kinases

Protein kinases regulate a great variety of cellular processes. More than 600 have been identified within the human genome. About 100 of them are calmodulin-dependent; they are involved in the regulation of numerous central cellular functions (see Swulius and Waxham, 2008 for a comprehensive review).

Figure 5 Schematic representation of a mitochondrion and its Ca^{2+} transporting systems. Details are found in the text. OMM is the outer mitochondrial membrane, IMM is the inner mitochondrial membrane, IMS is the inter membrane space. TCA is the citric acid cycle, which is also regulated by Ca^{2+} in the matrix. The cartoon also shows the endoplasmic reticulum closely associated with the mitochondrion and its two receptor/channels (InsP₃ R and RyR) that liberate Ca^{2+} to create micropools in which its concentration can temporarily reach the values well above micrometer necessary for the activation of the low affinity MCU uniporter. Other nonspecific channels (VDAC, mPTP) not described in the text also mediate the passage of Ca^{2+} under special conditions. Modified from Brini, M., Ottolini, D., Cali, T., 2013a. Intracellular calcium homeostasis and signaling. In: Banci, L. (Ed.), *Metallomics and the Cell, Metal Ions in Life Sciences*, vol. 12. Dordrecht: Springer Science + Business Media, pp. 119–168.

All members of the CaM kinase family are Ser/Thr kinases. Their general substrate consensus sequence is R-X-X-S/T (Kennelly and Krebs, 1991). According to their substrates they can be divided into two categories: monosubstrate and multisubstrate. MLCK, phosphorylase kinase, and CaM kinase III (elongation factor 2 kinase) are examples of monosubstrate kinases, whereas CaM kinase I, II, IV, and the CaM kinase-kinase (CaMKK) are multisubstrate kinases. The general structure of the CaM-kinases consists of a catalytic domain followed by a regulatory domain which contains both an auto-inhibitory and a CaM-binding domain.

The best understood CaM-dependent kinase at the molecular level is MLCK. It catalyzes the phosphorylation of a specific serine residue of the regulatory light chains of myosin II. Two MLCKs are encoded by different genes, and are specific for skeletal or smooth muscles (skMLCK and smMLCK). Both are important for the regulation of muscle contraction, however, the latter is also expressed in non-muscle cells.

Phosphorylase kinase is one of the largest and structurally most complex CaM-kinases. Its function is the phosphorylation of glycogen phosphorylase, the enzyme that modulates the energy source for muscle contraction. Phosphorylase kinase is composed of four subunits (α , β , γ , δ) that assemble in a heterotetramer of which four heterotetramers form the holoenzyme (molecular weight about 1.3 MDa). The γ subunit contains the catalytic core, whereas the α , β , and δ subunits are involved in the regulation of the enzyme. The δ subunit is CaM stably bound to the holoenzyme (Picton *et al.*, 1980).

A very special CaM kinase is CaMKIII, which phosphorylates elongation factor 2 as its only substrate (Nairn and Palfrey, 1987). Since its domain organization differs from that of CaMKI, II, or IV, CaMKIII has been renamed as elongation factor 2 kinase (EF2K). Phosphorylation of EF2 by EF2K leads to suppression of protein translation by the dissociation of EF2 from the ribosome.

CaMKI, II, and IV are multisubstrate kinases. CaMKI and IV are part of a phosphorylation cascade, since they are substrates of CaMKK β (Lee and Edelman, 1994; Tokumitsu *et al.*, 1994). They become fully active upon phosphorylation by CaMKK (CaMKKs are themselves substrates of other kinases, e.g., cyclin-dependent kinase 5, glycogen synthase kinase 3, and also DAPK). One of the best-studied substrates of CaMKI and IV is the transcription factor CREB, originally identified as a substrate of the cAMP-dependent protein kinase, but later shown to be an equally important substrate of CaMKI and IV in the control of Ca^{2+} -dependent gene expression (Matthews *et al.*, 1994).

CaMKI is ubiquitously expressed (the 3D structure of the autoinhibited form has been solved, Goldberg *et al.*, 1996). In contrast, the expression of CaMKIV is restricted to the nervous, immune, and fertilization systems (Wang *et al.*, 2001). Interestingly, recent observations have shown that CaMKIV is also involved in the regulation of alternative splicing (Xie and Black, 2001) of one of the isoforms of the PMCA pump, PMCA1a (Krebs, 2014), which is preferentially expressed during brain development.

CaMKII is very important for the regulation of synaptic plasticity and spatial memory (Giese *et al.*, 1998). In mammals four isoforms are encoded by different genes. In contrast to CamKI and IV, which are monomeric, the holoenzyme of CaMKII is a 12 subunit homo- or heteromeric complex. Autophosphorylation is important to CaMKII's activation, which is initiated by the Ca^{2+} -promoted binding of CaM, which releases the autoinhibited state (Hudmon and Schulman, 2002). Trans-phosphorylation between two adjacent Ca^{2+} /CaM-bound subunits generates a Ca^{2+} -independent activity, which enables the enzyme to decode the Ca^{2+} signals (Hanson *et al.*, 1994) necessary for synaptic plasticity, learning, and memory (Giese *et al.*, 1998). CaMKII's ability to detect changes in the frequency of Ca^{2+} oscillations has led to the suggestion that CaMKII may act as a trigger for synaptic plasticity (De Koninck and Schulman, 1998). Structural studies have added information on the regulation of neuronal (and cardiac) Ca^{2+} signaling by CaMKII (Stratton *et al.*, 2013).

Kimchi and coworkers have described a novel CaM Ser/Thr kinase (Deiss *et al.*, 1995), which is involved in the cell-death signaling network (DAPK). It was later demonstrated that DAPK belongs to a larger family of kinases, which are linked to apoptotic pathways. DAPK contains a conserved CaM autoregulatory domain with an inhibitory autophosphorylation site (Temmermann *et al.*, 2013). All members of this family of kinases can function as tumor suppressors, and possess regulatory domains important for function and localization within the cell (Shiloh *et al.*, 2014).

Calmodulin-Dependent Phosphatase

CaN is a 2B phosphatase regulated by CaM (Klee and Krinks, 1978), which is highly conserved from yeast to mammals. In mammals CaN is mainly found in the nervous tissues, hence its name (Klee *et al.*, 1979). The enzyme is composed of a catalytic domain CaN A that binds CaM and a regulatory domain CaN B, which itself is a CaM-like Ca^{2+} -binding subunit containing four EF-hands. The enzyme is rather substrate-selective, a major substrate being the nuclear factor of activated T-cells (NFAT). This highly phosphorylated transcription factor is dephosphorylated by CaN, which promotes its translocation to the nucleus (Jain *et al.*, 1993). An important finding was the demonstration that the immunosuppressants cyclosporin A and FK506 bind CaN with high affinity, inhibiting its phosphatase activity in T lymphocytes (Fruman *et al.*, 1992). The solution of the crystal structure of CaN bound to FK506 associated to its immunophylin FKBP12 has underlined its importance for the immune response (Griffith *et al.*, 1995; Kissinger *et al.*, 1995). In addition to Ca^{2+} /CaM, CaN is also regulated by an endogenous modulator, the regulator of calcineurin RCAN, a highly conserved protein whose gene is located in the critical Down Syndrome region of chromosome 21 (Fuentes *et al.*, 2000).

The Dark Side of Ca^{2+} Signaling: Ca^{2+} -Related Pathologies

One distinctive property of the Ca^{2+} signal is ambivalence. As should have become evident from the discussions above,

the Ca^{2+} message must be spatially and temporally controlled with great precision to permit the correct functioning of the most important processes of cell life. Unfortunately, the control may sometimes become defective, effectively transforming Ca^{2+} into a negative messenger: the uncontrolled activation of potentially harmful Ca^{2+} controlled activities, from proteases, to phospholipases, to nucleases, may create situations of cell discomfort that can in extreme cases culminate in cell death. In principle, death is not necessarily a negative phenomenon, as it is for instance essential for processes as organ remodeling and cell renewal, and is thus but one of the processes in which the Ca^{2+} signal operates under strict control. Conditions in which the control of the Ca^{2+} signal becomes grossly defective instead lead to the massive and global increase of cell Ca^{2+} and rapidly terminate cell life. These are the relatively uninteresting cases of toxic cell death. However, the dysregulation of the Ca^{2+} signal could also selectively affect individual components of the systems for its control; cell life would in these cases be permitted to continue, although with variable degrees of difficulty. These conditions are frequently genetic, and their study has now progressed to impressive molecular detail. A full discussion of Ca^{2+} related pathologies would be outside of the scope of this article, as the area has rapidly grown to be very large, and is extensively covered in a number of comprehensive contributions (see the additional readings suggested). These pathologies could affect practically every one of the systems that control Ca^{2+} by mediating its transport across membranes or by binding it for buffering purposes and/or to decode its message. Their study has offered interesting contributions to the understanding of the mechanisms for the control of cell Ca^{2+} and of the molecular processing of its message.

Glossary

Exportins and Importins (also known as karyopherins) They are the principal cargo receptors that recognize transport motifs in one compartment (nucleus or cytoplasm), interact with the nuclear pores, and then translocate across the pore. Their ability to bind cargo is sensitive to the GTP/GDP status of the Ran GTPase.

Nuclear envelope The double membrane that surrounds the nucleoplasm. The outer membrane is compositionally and functionally very similar to the endoplasmic reticulum.

Nuclear pores These are the eightfold symmetric mega-structures that are embedded in the nuclear envelope. All rapid transport into and out of the nucleus occurs through these pores.

Nucleocytoplasmic transport The process by which macromolecules translocate across the nuclear envelope.

Ran cycle The Ran GTPase belongs to the Ras superfamily. Its GTP/GDP state is critical for nuclear import and export.

Translocon The site in a membrane through which macromolecular transport occurs. Translocons of the nuclear envelope are nuclear pores.

Introduction

Because membranes form barriers between the interior and exterior of cells and between compartments within cells, the transport of macromolecules across membranes has been a classic object of study. Their elucidation has drawn from the fine application of genetic, biochemical, and cytological approaches. The understanding of corresponding mechanisms and their relation to transmembrane asymmetry lie at the heart of explaining the integrity and origin of highly differentiated multi-organelle eukaryotic cells.

History – Overview

Since transcription occurs in the nucleus, while most RNA resides in the cytoplasm where protein synthesis occurs, it was evident for many years that mechanisms must exist to export RNA and to import proteins. The first glimmer of understanding depended on the development of the electron microscope and satisfactory procedures for sample preparation, which made it possible to visualize nuclear pores (Hoelz *et al.*, 2011; Floch *et al.*, 2014; Figure 1). In fact, light microscopy can often predict the location of pores since

heterochromatin is absent from the regions of the nuclear perimeter where pores are inserted. Table 1 provides a chronology of relevant landmark observations that preceded investigations of nucleocytoplasmic transport per se.

Following upon the functional studies that defined some of the basic features of import, pore proteins were identified by purifying nuclei, recovering an insoluble residue after treatment with nucleases, detergent, concentrated salt and chelators, and using the residue to raise corresponding antibodies. When recovered from animal cells, the residue generally included the nuclear lamina as well as the pores themselves. The structure came to be known as the ‘nuclear pore complex’ (NPC) (Davis and Blobel, 1986; Dingwall and Laskey, 1986).

The distribution of ~100 (yeast) to thousands (animal cells) of pores along the surface of the nuclear envelope (NE) appears largely random; however, each pore often seems to define a territory that is free from other pores. Moreover, at least in *Saccharomyces cerevisiae*, NPCs are absent from the point at which the nucleus and vacuole contact each other (Pan *et al.*, 2000) and from multilayered regions of the NE (Wright *et al.*, 1988). Especially high-packing densities are characteristic of the NE of amphibian oocytes and portions of the NE of mature spermatids (Goldberg *et al.*, 1997;

Figure 1 Electron micrographs of animal cell nuclei. (a) A transmission EM of a thin section of a myeloma cell. Pores are circled in red. (b) A scanning EM image of the surface of the NE of a serous cell from the submandibular gland, prepared by osmium maceration (Riva *et al.*, 1998). (c) and (d) Scanning EM images of the cytoplasmic and nucleoplasmic faces of an isolated nuclear envelope from the oocyte of *Xenopus*. Each pore complex measures ~100 nm in diameter. Table 1 Setting the stage for discovery of nuclear pores

Nucleated fragments of cells can divide	Waller, Brandt, Nussbaum, and Gruber	1852–85
DNA is in the nucleus and RNA in the cytoplasm	Brachet and Caspersson	1933
First commercial transmission and scanning electron microscopes	Siemens, IG Farben, and Cambridge Instruments	1939–65
The nucleus programs cell phenotype	Hämmerling	1943
The transforming substance is DNA	Avery, MacLeod, and McCarty	1944
Phage transfer DNA into bacteria	Hershey and Chase	1952
Discovery of mRNA in bacteria	Brenner, Jacob, Meselson, and Monod	Late 1950s
EM visualization of pores in whole mounts and in thin sections	Callan and Tomlim; Scheer and Franke; Gall, Watson, Afzelius, and Rhodin	1950–66
Demonstration of nuclear synthesis of RNA, RNA export, and protein import and export	Prescott and Goldstein and Plaut	1955–67
Visualization of pores by freeze fracture	Friend and Fawcett	1974
Visualization of the nuclear basket by scanning EM	Ris	1989

Ho, 2010). In higher eukaryotes, pores are linked to the nuclear lamina and are not mobile in the plane of the membrane. By contrast, lateral translocation is evident in *S. cerevisiae* (Bucci and Wente, 1997; Belgareh and Doye, 1997) in which the inner face of the NE lacks lamin homologs (Hattier *et al.*, 2007; Gruenbaum *et al.*, 2005; Worman, 2012).

Abundant bidirectional translocation occurs through NPCs. Electron microscopic observations of colloidal gold tracers decorated with classical import or export cargos show that NPCs can transport cargo and can simultaneously participate in both import and export (Dingwall and Laskey, 1986; Feldherr and Dworetzky, 1988). The larger issue of the valency of translocation, i.e., whether more than two cargos can simultaneously pass in one or both directions, has not been addressed.

NPCs allow facile exchange of proteins <20–40 kDa, while larger protein cargos up to ~1000 kDa can enter if they carry nuclear localization signals (NLSs) that are accessible on their surface (Shulga *et al.*, 2000; Lanford *et al.*, 1986). By contrast to the cargos that access the endoplasmic reticulum (ER) or mitochondria, there is no need for the signals to be in the linear sequence of the cargo. Viruses that dock at the outer surface of NPCs as they import their genetic material may exceed the upper size limit. The entire NPC structure appears to be ‘belted’: No circumstances are known to change its external diameter. The striking observation that the NPC can accommodate huge cargos without being grossly leaky for monomeric proteins suggests that cargo in transit is in some way sequestered or intimately enclosed in a malleable milieu (see below).

Since NLSs and nuclear export signals (NESs) are not removed upon translocation, individual cargos can be translocated repeatedly, as for transcription factors that shuttle across the NE (Kopito and Elbaum, 2007). For cells that undergo NE breakdown during mitosis, the permanence of signals enormously facilitates the reestablishment of the nucleoplasmic milieu in telophase.

In addition to the translocation of soluble cargos, as discussed below, the NPC mediates transport of membrane proteins. Thus, proteins delivered to the ER membrane access the inner (and outer) membrane of the NE, and proteins of the inner membrane can access the ER (Powell and Burke, 1990). These events may result from traversal of a lateral channel at the margin of the NPC. Import of inner membrane proteins is facilitated by NLSs that are also functional for soluble cargos (Lusk *et al.*, 2007; Schirmer *et al.*, 2003).

Transport Signals and the Importin β Superfamily: A Code

Many NLS motifs are enriched in positively charged amino acids. These ‘classical’ signals can be monopartite, as in SV40 large T antigen, or bipartite, as in nucleoplasmin. Their identification – and the demonstration of ongoing import of proteins – largely depended on studies in which candidate cargos were delivered into the cytoplasm of *Xenopus* oocytes and then were followed to evaluate their import into the nucleus (Dingwall and Laskey, 1986; Goldfarb *et al.*, 1986; Stevens and Swift, 1966; Speer and Zimmerman, 1968; Bonner, 1975; Kalderon *et al.*, 1984). Initially it was unclear

whether corresponding receptors were in fact permanent components of the NPCs or rather might be soluble in the cytoplasm. It was also unclear as to whether filamentous docking sites might extend throughout the cytoplasm (and nucleoplasm) to facilitate cargo delivery to the NPC.

After attempts to use NLSs as probes for binding factors and for affinity retrieval, proper identification of receptors required development of a functional assay for import. This depended on the all-important realization that treatment of adherent cells in culture with the sterol-selective detergent, digitonin, permeabilized the plasma membrane, releasing soluble proteins, and exposing the surface of the nucleus. Since import of labeled cargos could be beautifully reconstituted by addition of cytosolic proteins, this assay was used to identify the essential equipment for import: importin β /karyopherins and the GTPase, Ran (Moore and Blobel, 1992; Fornerod *et al.*, 1997b; Gorlich *et al.*, 1997; Adam *et al.*, 1990).

Importin β superfamily members (KAPs, IPOs, and XPOs – 95–145 kDa) have a ‘Ran-GTP binding domain’ at their N-terminus, that is followed by many short α -helical ‘HEAT repeat’ motifs that bind both translocation cargos and the NPC (Strom and Weis, 2001; Kimura and Imamoto, 2014). Crystallographic studies have defined cargo-binding sites for several importins and exportins in great detail (Suel *et al.*, 2006; Cook *et al.*, 2007).

In the widely accepted model for import, cargos with classical NLSs bind complementary sites in adaptor proteins (importin α ’s – that are not members of the importin β family; Goldfarb *et al.*, 2004) that in turn bind importin β 1 (KPNB1), thus making it possible to interact with and traverse the NPC. Proteins with nonclassical NLSs bind directly to and are translocated by other members of the importin β family (Table 2; Figure 2). The recognition code for transport is in many cases degenerate: multiple cargos bind the same importin and some cargos bind to more than one importin. In fact, the varieties of signals that are recognized by many importins have not yet been exhaustively characterized and it remains in many cases quite unclear why individual cargos use one or another signal/importin pair. It is not evident, for example, that groups of proteins that are functionally related are generally imported by a single importin.

Several approaches have been used to identify the cargo that is transported by a given importin β . If an importin can be inactivated (using ts alleles or promoter shut off) one can ask whether the nucleocytoplasmic distribution of a given potential cargo will change upon inactivation. Such evidence is indirect, but strongly suggestive of function. More direct approaches have involved expressing a given importin β in living cells, recovering it from lysates, and then inquiring whether any putative cargo can be released from it upon denaturation. Since the GTPase, Ran, cycles between GTP- and GDP-bound forms (see below), this test becomes definitive if the release of cargo is achieved by the addition of Ran-GTP or a Ran mutant that is locked in the GTP-bound conformation. For exportins, a reciprocal strategy can involve binding in the presence of Ran-GTP and then inquiring whether a cargo is released upon addition of Ran-GAP or replacement of Ran-GTP with Ran-GDP.

Many export cargos are correspondingly translocated by ‘exportins,’ that belong to the very same importin β

Table 2 Importin β family members and typical cargos

	Importin/exportin		Known cargo	
	Homo sapiens	Saccharomyces cerevisiae	H. sapiens	S. cerevisiae
Import	<i>Homologs are readily identified^a</i>			
	KPNB1/ β 1	KAP95	Importin α and associated proteins with classical monopartite NLSs, snurportin	
	IPO9	KAP114	Actin, histones, ribosomal proteins	H2A, H2B, Nap1, Spt15, Sua7
	IPO11	KAP120	L12, UbcM2	Rfp1
	IPO4	KAP123	RPS3A, UL84	H3, H4
Export	XPO5	MSN5/KAP142 (bidirectional)	dsRNA export, microRNAs	Import of Rfa1; export of Far1, Msn2, Pho4, Swi5, Swi6, large subunits, tRNAs
	CSE1L	CSE1/KAP109	Importin α	
	XPO1	LOS1	tRNAs	
Import	<i>Diversification^a</i>

^aGroupings are according to whether the structure of each importin is widely conserved (Quan *et al.*, 2008).

Note: Cargos remain to be identified for many family members.

Figure 2 Overview of nuclear import and export. Membrane surfaces are designated by horizontal lines. The paired sets of black arrows designate the arrival of multiple importins (or exportins) which is followed by their return to their compartment of origin. The red arrows indicate the location of cargo after release from the translocon. o.m., outer membrane; i.m., inner membrane.

superfamily (Guttler and Gorlich, 2011). This elegant structural convergence between importins and exportins is remarkable. 'Leucine-rich' NESs bind the exportin, Crm1/XPO1. This cargo motif-exportin pair was identified as a result of interest in localization of incompletely spliced HIV mRNAs and a subunit of cAMP-dependent protein kinase, as well as identification of the target of the anti-HIV drug, leptomycin B (Fischer *et al.*, 1995; Kutay and Guttinger, 2005; Wen *et al.*, 1995; Fornerod *et al.*, 1997a; Fukuda *et al.*, 1997). Crm1 is responsible for the export of many proteins of diverse biological significance, as well as several types of RNPs (Table 3). Its name belies its initial identification as a protein that is important for 'chromosomal region maintenance' in *Schizosaccharomyces pombe* (Adachi and Yanagida, 1989).

Exportin-t/Los1 is one of several factors that contributes to export of tRNAs (Arts *et al.*, 1998; Lipowsky *et al.*, 1999; Hopper *et al.*, 2010). Perhaps because of their large size, several exportins and at least one 'mRNA export factor,' Mtr2/Mex67, contribute to ribosomal subunit export (Lo and Johnson, 2009; Woolford and Baserga, 2013; Wild *et al.*, 2010).

Table 3 Mediators of RNA export^a

Class of RNA	Export factors/binding factors
<i>Importin/exportin-related</i>	
rRNA, large subunit	Crm1, XPO5, Mtr2/Mex67, Arx1, Nmd3
rRNA, small subunit	Crm1
5s RNA	La, LS, TFIIA
tRNAs	XPO5, Los1, PAUSED
snRNAs	Crm1, PHAX, CBP
microRNA precursors	XPO5
<i>Independent of importins/exportins</i>	
mRNAs	Mex67/Mtr2 (TAP/p15) and special cases

^aKohler and Hurt, 2007; Taniguchi *et al.*, 2014

In generating these subunits, the nucleolus provides an example of massive transcription, RNP processing, intranuclear transport, and export. Localization of individual components that accomplish these events has defined the contiguous sub-compartments that are involved. Interestingly, the nucleolus is often associated with the inner aspect of the NE (Oakes *et al.*, 1998; Bourgeois *et al.*, 1979).

The repeated use of importins and exportins for successive translocation events mandates that there must be efficient mechanisms to normalize their distribution after release of their cargos (see below for a discussion of protein shuttling per se). One well-studied example of reexport of an import carrier is that of importin α , whose reexport is mediated by the exportin, Cse1. It is not known whether single carriers normalize the distribution of multiple importin family members.

There are also striking examples of nucleocytoplasmic transport that do not directly involve importin family members (Kumeta *et al.*, 2012). These include the import of Ran-GDP itself, that is mediated by Ntf2 (Ribbeck and Gorlich, 2002), import of β -catenin, and mRNA export (see below).

Directionality of Translocation by Importin β Superfamily Members

Cargo translocation by importin β 's occurs in conjunction with the Ras superfamily GTPase, Ran, that cycles between its GDP-bound form (in the cytoplasm) and its GTP-bound form (in the nucleus), due to the polarized distribution of Ran-GAP (GTPase activating protein) and the corresponding guanine nucleotide exchange factor (RanGEF). Ran-GTP confers directionality upon translocation by controlling the conformation of importin β 's, thereby regulating their affinity for cargos. Thus, once inside the nucleus, the binding of Ran-GTP to import complexes (cargo bound to an importin β) causes cargo release – sometimes with the participation of additional cofactors. By contrast, Ran-GTP binding to export complexes (cargo bound to an exportin) in the nucleus stabilizes the complexes until they arrive at the cytoplasmic surface of the NPC, where Ran-binding proteins cause release of Ran-GTP that is rapidly hydrolyzed by local Ran-GAP. Transit of protein cargos through the NPC is not obligatorily coupled to ATP or

GTP hydrolysis. Studies of several cargos show that the only energy requirement for importin-mediated nucleocytoplasmic translocation is due to the need to replenish Ran-GTP (Englmeier *et al.*, 1999; Ribbeck *et al.*, 1999; Schwoebel *et al.*, 1998). Net accumulation of many cargos on one side of the NPC thus requires their binding to targets that are selectively concentrated on the same side. It nevertheless remains possible that especially large cargos present further energy requirements.

Although Ran/TC4 was already known to affect RNA metabolism, DNA synthesis, and cell cycle control (Bischoff *et al.*, 2002), its relation to nucleocytoplasmic transport depended on discovery of its GEF in *S. cerevisiae* (Mtr1/Prp20) as a protein whose mutation causes nuclear accumulation of poly (A) + RNA (Kadowaki *et al.*, 1992; Amberg *et al.*, 1993). Mutations in what proved to be the corresponding Ran-GAP, Rna1, had a comparable effect. Moreover, hamster cells that carry a ts mutation in a homolog of Mtr1/Prp20 – first characterized because they cause premature chromosome condensation (Nishimoto *et al.*, 1978) – also accumulate poly (A) + RNA in the nucleus at the restrictive temperature. In-depth investigation of the Ran cycle was inspired by studies of Ras. This precedent provided quantitative assays for measuring the regulation of GTPase activity and made it evident that specific Ran mutants would be able to mimic the normal GTP- or GDP-bound conformations of Ran.

At least two members of the importin β superfamily (importin 13 (in man), Msn5 (in yeast)) can mediate cargo translocation in both directions. There has been no investigation of the structural correlates of this bidirectionality.

Apart from the issue of whether a given carrier normally translocates distinct cargos in both directions, there is the question of whether a carrier can be caused to translocate the same cargo both into and out of the nucleus. Since translocation requires docking at the NPC, and since the nucleocytoplasmic distribution of nucleoporins is in part asymmetric, one might expect such net reversal to be impossible. Nevertheless, experimental inversion of the Ran-GTP/Ran-GDP gradient can cause Crm1 to function as an importin (Nachury and Weis, 1999). This apparently symmetric performance of the NPC could reflect the relative nonspecificity of importin interactions with the FG-rich internal milieu and/or the observation that many nucleoporins reversibly dissociate from and reassociate with the NPC (Rabut *et al.*, 2004).

mRNA Export

The structural diversity of mRNAs poses a major challenge for their recognition (Wickramasinghe *et al.*, 2014; Ohno *et al.*, 2002). In the best-studied cases, rather than depending on exportins, export is accomplished by a complex set of proteins that bind transcripts during their transcription, while others are added during their covalent maturation (Rodriguez-Navarro and Hurt, 2011; Kyllberg *et al.*, 2008; Natalizio and Wente, 2013). Moreover, interestingly, covalently mature transcripts can be exported upon microinjection into the nucleus. Export of many mRNPs after splicing is mediated by Aly/REF and shuttling SR proteins, followed by intervention of Mex67p/TAP in conjunction with Mtr2p/p15. Release of the

mRNA cargo to the cytoplasm is then due to the activity of the RNA helicase, Dbp5, that is concentrated at the cytoplasmic surface of NPCs and could serve as a ratchet, roughly analogous to the *trans* factors that account for protein import into mitochondria. Inositol phosphates and Gle1 play a central role in these events (Ledoux and Guthrie, 2011; Tseng *et al.*, 1998; Natalizio and Wente, 2013; Schmitt *et al.*, 1999). After cargo release, reimport of mRNA export factors is mediated by the importin, Mtr10, that also functions in reimport of tRNAs (Pemberton *et al.*, 1997; Senger *et al.*, 1998; Hopper *et al.*, 2010).

Remarkably, it has been possible to visualize selected large mRNPs as they are exported through the nuclear pores in insect salivary glands (Kylberg *et al.*, 2008).

Identification of mRNA export factors initially was made possible by generation of corresponding temperature-sensitive mutants of yeast. The key requirements for this undertaking were development of a reliable *in situ* hybridization procedure to detect accumulation of poly(A)⁺ RNA in the nucleus and the devising of appropriate genetic selections. Although some of the resulting lesions were in nucleoporins, others were in the dedicated equipment that manages mRNAs (Farny *et al.*, 2008; Katahira *et al.*, 1999; Kadowaki *et al.*, 1994).

It has not been possible to develop corresponding export assays using permeabilized animal cells, probably because of the need to ensure splicing (Lichtenstein *et al.*, 2001). Oocyte microinjection studies have been highly useful for investigation of mRNA export (Jarmolowski *et al.*, 1994; Ohno *et al.*, 2002; Taniguchi *et al.*, 2014).

Like mRNAs, small structured snRNAs undergo cap methylation; however, their export is mediated by specific associated proteins (PHAX, CBP) that interact with Crm1. Subsequent to export, the cap become trimethylated, the set of Sm proteins is added, and reimport occurs upon recognition by the β family member, snurportin in conjunction with KPNB1 (Matera and Wang, 2014).

Nucleoporins

The NPC consists of about 30 different nucleoporins (Nups). It has eightfold symmetry in the plane of the membrane – as was first recognized by Gall – and each of its proteins is therefore likely to be present in multiples of eight (Antonin *et al.*, 2008; Beck *et al.*, 2007; Lim *et al.*, 2008; Suntharalingam and Wente, 2003).

There are three classes of Nups: ‘structural Nups’ that contribute to overall NPC architecture; ‘pore membrane proteins’ (Poms), that include a transmembrane domain and could contribute to anchoring the NPC in the NE; and ‘FG-Nups,’ that include multiple clusters of phenylalanine-glycine (FG), GLFG, or FxFG repeat motifs that are interspersed among polar sequences. The FG-rich domains of Nups are unstructured and are essential for maintaining the NPC permeability barrier (Denning *et al.*, 2003). Many FG-Nups line the central NPC channel, while others are found in the asymmetric filaments and ‘nuclear basket’ that extend from the cytoplasmic and nucleoplasmic faces of the NPC. Interestingly, the basket anchors components of the SUMO modification cycle, mRNP surveillance factors and spindle assembly checkpoint proteins.

Although the filaments are not essential for survival, they can serve as docking sites for cargo–importin complexes (Richardson *et al.*, 1988; Walther *et al.*, 2002).

During translocation, the surfaces of importins and exportins are thought to engage in multiple low-affinity interactions with FG repeats. Whether they follow a specific sequence of stepping-stones or rather associate indiscriminately with hydrophobic elements in the NPC channel, has been a matter of dispute (Ben-Efraim and Gerace, 2001; Frey and Gorlich, 2007; Peters, 2005; Weis, 2007). Although the latter model has many strengths – and has become amenable to further scrutiny now that macroscopic FG-repeat-containing ‘hydrogel’ preparations are available – the surfaces of importins are by no means uniformly hydrophobic. Moreover, it seems unlikely that importins cover or conceal most of the surface of some cargos that they transport. Translocation through the FG-rich interior of the NPC has been described by a ‘virtual gate model,’ an ‘oily spaghetti model,’ a ‘selective phase model,’ and a ‘reduction of dimensionality model’ (Peters, 2005; Hulsmann *et al.*, 2012).

A more complete understanding of translocation will depend on both the bottoms-up approach of studying small cargos and a top-down emphasis on the huge cargos that presumably were the *raison d’être* of the evolution of the NPC. Any satisfactory model will have to take into consideration the dynamic nature of the NPC itself since many nucleoporins frequently detach from the NPC, possibly as a result of transport of especially large ribonucleoprotein cargos (Rabut *et al.*, 2004). Crystallography of subcomplexes of nucleoporins, as well as methods to tag single cargo molecules, importins and nucleoporins, will surely refine present models of the NPC and understanding of translocation. A major present goal is to obtain a full 3D structure of the NPC, making use of preparations from vertebrates and fungi, including thermophiles. This work is discussed at length in (Aitchison and Rout, 2012) and in the article by Imamoto.

Regulation of Transport

The specificity of cargo–importin interactions raises a fundamental quandary: since many proteins are imported even though they do not share identical motifs, the overall scope of substrate recognition by importins must be broad. Moreover, many proteins of modest size equilibrate across the NE. Thus, at least selected cytoplasmic proteins could wreck havoc if they entered the nucleus. There therefore must be mechanisms that regulate transport in both directions. It is perhaps for this reason that multiple transport signals are often found on many single cargos. Moreover, the activity of transport signals is often regulated by their phosphorylation, acetylation, ubiquitylation, or methylation. Their activity can also be regulated by signal concealment, as for the transcription factor, NF- κ B, that cannot be recognized by importins until its inhibitory subunits have been removed, or for p53, that conceals its NESs when induced to form a tetramer and activate transcription. Interestingly, some translocation signals overlap with domains that have a distinct functional importance. A good example is that of homeobox proteins for which NLSs are situated within the DNA-binding homeodomain itself. Transport can also be

regulated by tethering to cytoplasmic structures, as for the transcription factor, SREBP, that is a transmembrane protein of the ER until released by proteolysis.

The issue of signal concealment and modulation is especially conspicuous for RNPs whose proteins are imported into the nucleus where they are assembled with RNA prior to export (SRP, ribosomal subunits, etc.). Were the multiple NLSs of their proteins to remain exposed after export, these RNPs could well sequester import factors or undergo repeated import.

With regard to global regulation of the transport equipment, phosphorylation of yet unidentified components of the nuclei of digitonin-permeabilized cells affects import (Kehlenbach and Gerace, 2000). Other studies indicate that the diffusional diameter of the NPC and its composition are affected by transformation and during the cell cycle (Feldherr *et al.*, 1998; Makhnevych *et al.*, 2003). Additionally, the cell cycle regulatory protein, Mad1 (that associates with NPCs), regulates both Kap121 and the spindle assembly checkpoint (Cairo *et al.*, 2013; Rodriguez-Bravo *et al.*, 2014). Furthermore, several viruses cause selective destruction of Nup's or interfere with the Ran cycle.

Individual nucleoporins are unevenly expressed among distinct cells types. Moreover, the relative titer of importin β proteins and transcripts varies among cell types and changes during development (Kimura and Imamoto, 2014; Quan *et al.*, 2008). As an extreme example of differential function, the macro- and micronuclei of protozoa express distinct sets of nucleoporins and use different subsets of importins (Malone *et al.*, 2008).

Shuttling

Although most of the transport options described above are unidirectional, many proteins – and even tRNAs and several snRNAs (Hopper *et al.*, 2010) – can be both imported and exported. There is no evidence for such recurrent import and export for the ER or mitochondria. For peroxisomes, at least some carriers do appear to enter and then return to the cytoplasm.

Shuttling between nucleus and cytoplasm can result from successive interactions with distinct importin family members, in which case the cargo has both NLS and NES motifs (Stade *et al.*, 1997). Alternatively, transport in one direction can be passive, as for proteins that are small enough to exit by diffusion through the NPC (Shulga *et al.*, 2000).

For proteins that are highly concentrated in the nucleus, a classical strategy to document shuttling has involved the formation of dikaryons (or multikaryons) as a result of cell–cell fusion. One then inquires whether a macromolecule that is initially present in the nucleus of only one of the two cell types will become detectable also in the second type of nucleus. In such protocols it is critical to stop new synthesis of the cargo in question. Yeast provides a novel way to generate dikaryons by studying zygotes in crosses of *kar1* mutants with wild-type cells. The *kar1* mutants of interest oppose most congression of nuclei after cell–cell fusion (Liang *et al.*, 1996; Flach *et al.*, 1994).

For proteins that are concentrated in the cytoplasm, one could use photobleaching to document repeated entry. Thus, if these cargos are fluorescent, iterated bleaching of the nuclear content would bleach the intranuclear pool and ultimately also deplete the cytoplasmic signal.

Related Issues/Unanticipated Roles of the Nucleus

Related aspects of transport have also been intensely investigated. These include

- The disassembly and ordered reassembly of NPCs during each cell cycle as the NE and lamina break down and reform in higher eukaryotic cells. Moreover, in growing cells, newly synthesized nucleoporins are continually added to existing NPCs (Antonin *et al.*, 2008; Wandke and Kutay, 2013; Rothballer and Kutay, 2013; Doucet and Hetzer, 2010). Interestingly, NPC assembly can regulate abscission at the end of the cell cycle (Mackay and Ullman, 2011).
- The importance of Ran-GTP in associating with chromatin and promoting assembly of the spindle, the NE and NPCs (Hetzer *et al.*, 2002; Walther *et al.*, 2003; Zheng, 2004).
- The reversible sequestration of many proteins in the nucleolus. One example is that of the key cell cycle regulatory phosphatase, Cdc14, that resides in inactive form in the nucleolus until it is progressively released to the nucleoplasm and cytoplasm in anaphase (Manzoni *et al.*, 2010; Audas *et al.*, 2012).

Other less-investigated areas concern

- Signaling, both across the inner nuclear membrane, which may involve SUN/KASH proteins, and also between the nucleoplasm and the vacuole at their site of mutual contact – the nucleus–vacuole junction (Pan *et al.*, 2000).
- Issues of stoichiometry and scale that define the surface area of the NE (Arnone *et al.*, 2013; Hattier *et al.*, 2007; Kessel, 1992; Ralle *et al.*, 2004), the stoichiometry of nucleoporins (some of which are remarkably long-lived; Savas *et al.*, 2012), and the number and turnover of NPCs.
- Turnover of cytoplasmic proteins inside the nucleus (Park *et al.*, 2013) and turnover of parts of the nucleus by 'piecemeal' autophagy (Krick *et al.*, 2008) as well as full nucleation (Keerthivasan *et al.*, 2011).
- Apparent perforation of the NE in laminopathies and upon aging (De Vos *et al.*, 2011; D'Angelo *et al.*, 2009), and as a means of releasing large particles into the cytoplasm (Speese *et al.*, 2012; Buser *et al.*, 2007; Afzelius, 1963).
- The mechanisms of nuclear fusion, in which the outer membranes fuse before the inner membranes, ultimately allowing encounter of parental genomes (Melloy *et al.*, 2007; Tartakoff and Jaiswal, 2009).
- Regulation of gene expression by NPCs and the NE (Kohler and Hurt, 2010; Bermejo *et al.*, 2012; Ishii *et al.*, 2002).

Evolutionary Considerations

Nuclear Envelope

In an attempt to explain the origin of the NE, many authors envisage the envelopment of genomic DNA nucleoids by elements of an endomembrane system related to the ER, causing the genome to be bounded by a double membrane. This model is directly reminiscent of both the wrapping of chromatin that occurs during anaphase of higher eukaryotes, and the

experimental generation of 'artificial nuclei' (with pores) upon incubation of chromatin (or DNA) in extracts of *Xenopus* oocyte cytoplasm (Richardson *et al.*, 1988; Bernis and Forbes, 2014; Newmeyer *et al.*, 1986). A number of prokaryotes have membrane-bounded internal compartments that surround nucleoids; however, they are not fully closed (Fuerst, 2005).

One way to account for the presence of pores is to postulate that the endomembrane in question already included structures related to annulate lamellae or was fenestrated, as are distal cisternae of the Golgi and *trans*-Golgi network. Alternatively, the extremities of the ER-related endomembrane, having already almost encircled the chromatin, could have been decorated with COPII components, as are the transitional elements that normally bud from the ER in the direction of the Golgi. If these coated elements could not fuse with each other, the result would be focal pores limited by COPII orthologs. This scenario could account for the presence of Sec13p both in the NPC and at transitional elements, and also for the presence of Nup's that share a domain with the COPII protein, Sec31p (Devos *et al.*, 2004; Brohawn *et al.*, 2008).

A related and critical aspect of this discussion concerns the origin of the inner membrane of the NE, that is distinct from the ER (Lusk *et al.*, 2007; Schirmer *et al.*, 2003). Among the few proteins of the NE that share motifs with prokaryotes are the proteins that include a HEH motif that is also found in prokaryotic DNA-binding proteins (Mans *et al.*, 2004; Ulbert *et al.*, 2006). The first appearance of membrane proteins that bind chromatin (or the nuclear lamina) could have been crucial for the development of an enclosed genome.

The presence of the nucleus could have made possible sequestration of genes that include introns, e.g. α -proteobacterial/promitochondrial genes that have type II self-splicing introns. Since intron-containing transcripts would code for nonfunctional truncated products, it is necessary to remove the introns before allowing translation. This condition is assured so long as the genome and splicing are segregated from translation, for example, by housing them in distinct compartments, while allowing selective nucleocytoplasmic transport to occur (Cavalier-Smith, 2005; Koonin, 2006; Lopez-Garcia and Moreira, 2006; Mans *et al.*, 2004).

Ran, Nucleoporins, and Importins

The appearance of Ran in evolutionary time may predate the rest of the equipment needed for nucleocytoplasmic transport, considering that the small GTPase superfamily of molecular switches is well-developed in prokaryotes (Jekely, 2003) and since Ran is also central to the organization of chromatin and the spindle. Ran lacks the C-terminal lipid moiety that is characteristic of Ras superfamily members that function in the cytoplasm. Considering the dynamic import and export of Ran, its lack of membrane anchoring is crucial.

Prokaryotes lack proteins closely related to nucleoporins and importins (Mans *et al.*, 2004). Their functional interdependence makes it highly likely that they coevolved, along with Ran (Stuwe *et al.*, 2014). Ongoing investigations, perhaps further advancing the pace of evolution of *S. cerevisiae*, have simplified the NPC by eliminating selected Nup's and removing some FG repeats from those that remain, to generate a 'minimal' NPC (Strawn *et al.*, 2004).

Comparative studies indicate that the most primitive eukaryote is likely to have had on the order of 13 nucleoporins, of which at least eight are present throughout eukaryotes (Mans *et al.*, 2004). Structural Nup's that lack repeats seem the most conserved, and a subset of them including Nup107, Nup160, and ELYS/Mel28 is also implicated in the initial steps of NPC assembly in vertebrates (Antonin *et al.*, 2008; Walther *et al.*, 2003). Orthologs of the Pom, Ndc1, are found in both yeast and vertebrates (but not in the primitive protest, *Giardia lamblia*). Ndc1 also is implicated in NPC formation (Mansfeld *et al.*, 2006). For FG-repeat Nup's, most of the sequences outside of the repeats appear especially variable, apart from those that mediate characteristic interactions (among Nup's, with importins, etc.) (Degrasse *et al.*, 2009; Denning *et al.*, 2003).

Importin β 's can be recognized from yeast to man (Strom and Weis, 2001) and in most species there are more importins than exportins. For example, in man there are 12 importins and 7 exportins. Among the 14 importin β s of *S. cerevisiae*, 10 can be matched with their human orthologs directly (Quan *et al.*, 2008). The C-terminal cargo-binding domain of one importin adapter, snurportin 1 (that imports snRNAs that have a tri-methyl cap, in conjunction with KPNB1), clearly is orthologous to the guanylyl transferase domain of the capping enzyme itself. The observation that no extant species has a small repertoire of importins implies that their multiplicity provides significant advantage.

As a trace of the possible prokaryotic origin of the machinery of export, the GTPases, Nug1p/Nug2p and Nog1p, that function in 60S ribosomal subunit export in eukaryotes, are orthologous to proteins that function in ribosome assembly in prokaryotes (Mans *et al.*, 2004).

The most primitive export equipment for mRNAs could have included proteins related to TAP/Mex67 and p15/Mtr2, considering their widespread distribution. Alternatively, there could have been 'urexportins' that bound Ran-GTP and mature mRNA transcripts. In this event, given the high prevailing GTP/GDP ratio of cells, the key element of directionality could have been provided by the emergence of a Ran equivalent and a cytoplasmic protein with Ran-GAP activity. Curiously, there are bacterial sterol isomerases that share a 'Ntf2 domain' with the Ran-GDP import factor, Ntf2. This motif is also characteristic of the export factors, Mtr2p and TAP/Mex67p (Mans *et al.*, 2004).

Translocons for Oversize Cargos

The need to accommodate large cargos could have first arisen to export RNPs from the nucleus. Other conspicuous examples of transport of oversize cargos are the entry of multisubunit complexes (and gold particles) into the peroxisome and the export of subviral particles from the ER. The fundamental characteristics of the corresponding transport channels could be quite distinct from each other. By contrast to the multi-spanning translocons of the ER, and the β -barrel translocon of the mitochondrion, such extreme distensibility is likely to be possible only when the channel is composed of multiple subunits whose positions relative to each other can be adjusted without dissipating the integrity of the mega-complex, perhaps because they are belted. In this regard, present models of the interior of the NPC envisage elements that self-associate, move relative to each other, and also bind importins, thereby being able to substitute one interaction

for the other. This type of organization would ensure a tight fit regardless of whether cargo is in transit.

Bacteria also translocate hetero-oligomeric and folded proteins. These pathways include (1) Type II secretion, in which cargos are first exported to the periplasmic space by SecY, where they fold and then are secondarily exported through the outer membrane channel formed by multimers of GspD and (2) TAT-dependent transport that is clearly related to the system that transports protein complexes into the thylakoids of chloroplasts. In this system, oligomerization of TatA is thought to generate the corresponding channel in the inner membrane. If this precedent is an accurate guide, the distensible channels of animal cells will also prove to be multimeric. When belted, such units begin to resemble the NPC.

Concluding Remarks

Shuttling between the nucleus and cytoplasm is integral to the organization of eukaryotic cells. It is gratifying to see that the fundamentals of these events have been extensively characterized in a few decades since discovery of nuclear pores. Exhilarating meetings, multiple reviews, and new journals have helped coordinate these efforts.

There are a vast number of specific applications of these fundamental observations and concepts for individual proteins, RNAs, and distinct cell types and organisms. As in much of cell biology, present understanding can be attributed to the application of biochemical, genetic, and cytological approaches. In many cases, this information makes it possible to understand malfunction that underlies disease. Reciprocally, investigations of the molecular basis of disease have often helped elucidate the basic mechanisms of nucleocytoplasmic transport.

Cell–Cell Adhesion: The Essence of Multicellularity

All animals begin their lives as single cells. Cell growth and division lead to multicellularity and expansion of the organism; concomitantly, cell differentiation gives rise to a variety of cell types with specialized functions. Nonetheless, it is cell adhesion that ultimately organizes these cells into tissues and organs, and unites them into a single organism. Depending on their type and location, cells in our body engage in interactions with other cells, and/or with the extracellular matrix surrounding them. For example, endothelial cells lining the interior of blood vessels interact with neighboring endothelial cells and with the basal lamina, whereas chondrocytes producing the cartilage between our bones interact only with the matrix they secrete, and are embedded within.

Interactions between a cell and its environment serve multiple purposes: they provide the cell with positional cues (e.g., apical/basal and front/back); they facilitate biochemical signaling (e.g., growth factors); and they enable mechanical coupling, important for regulating cell shape (e.g., spreading and polarity), for integrating cells into tissues, and for transforming cell dynamics into tissue dynamics (e.g., gastrulation and migration). Both cell–matrix and cell–cell adhesions are critical for the development and homeostasis of multicellular organisms. While they share many functions as well as molecular pathways, they also display distinct features. In this

article, we will focus our attention on cell–cell adhesions. Cell–matrix adhesions are discussed in a separate article.

The adhesion of one cell to another is not a spontaneous process. The plasma membrane itself is not ‘sticky,’ and the intrinsic contractility of cells acts to round their surfaces. Cell–cell adhesion is primarily achieved through the action of transmembrane adhesion receptors that counteract the cell’s surface tension by generating adhesion tension, and through regulation of the cortical cytoskeleton (Maitre and Heisenberg, 2013).

As will be elaborated on below, mammalian cells possess several different types of adhesion receptors. Each type clusters with receptors of the same kind to form distinct cell–cell adhesion sites, also referred to as cell–cell junctions. The formation of such junctions is nucleated by adhesion-independent nanoclusters of receptors that are delimited by the actin cortex (Wu *et al.*, 2015). The cytoplasmic tails of the receptors recruit adaptor proteins, which in turn bind a variety of structural, scaffolding, and signaling proteins that ultimately integrate the nascent adhesion site with the cytoskeleton (Garrod and Chidgey, 2008; Zaidel-Bar, 2013; Guo *et al.*, 2014). Signaling components play a dual role: they respond to extracellular signals to affect cell behavior, and they regulate cell adhesion in response to internal signaling.

As demonstrated in Figure 1, interactions between adhesion receptors of the same kind (homophilic) or of a

Figure 1 Different forms of cell–cell adhesions. Illustration depicting several possible modes of interaction between similar or different cells, mediated via similar or different adhesion receptors.

different kind (heterophilic) have been shown to mediate both interactions between cells of the same type (homotypic), and interactions between cells of different origins (heterotypic). It is important to note that while [Figure 1](#) highlights a specific example for each type of interaction, any two cells are likely to be interacting through multiple types of adhesion receptors.

The aim of this article is to provide molecular insights into the mechanisms by which the structural and signaling modules of cell–cell junctions function in tandem, in order to provide the cell with a responsive, dynamic junction that is fully integrated with the cell's activities and fate.

Structural and Functional Diversity of Cell–Cell Junctions

Cell–cell adhesions (=junctions) differ structurally, molecularly, and functionally, according to characteristic subcellular positions and functions. Based on their physiological role, cell–cell junctions can be broadly divided into three types: occluding, anchoring, and signaling ([Figure 2](#)).

Occluding junctions are only found in epithelial sheets, such as the lining of the gut and kidney, where formation of a barrier between the two sides of the monolayer is essential.

Proteins of the claudin and occludin family mediate occluding adhesions in invertebrate tight junctions ([Furuse et al., 1998](#)), and closely related proteins function similarly in invertebrate septate junctions. Tight junctions in invertebrates are located at the most apical position along the lateral membrane of neighboring cells. In addition to sealing the space between cells, tight junctions also create a ‘fence’ within the cell's membrane that helps to separate the apical and baso-lateral membrane domains ([Farquhar and Palade, 1963](#)).

The most ancient anchoring junction found in all animal cells is the adherens junction (AJ), which is based on cadherin adhesion receptors linked to the actin cytoskeleton ([Farquhar and Palade, 1963](#)). AJs provide a physical connection between cells of the body by reinforcing their cell–cell adhesions with the actomyosin cytoskeleton ([Yonemura, 2011](#)). In the following sections, we will focus on AJs, their receptors, their connection with the actin cytoskeleton, and regulation of their function by an ensemble of proteins we refer to as the ‘cadherin adhesome’ ([Zaidel-Bar, 2013](#)).

Unique to vertebrates is a second type of anchoring junction: the desmosome. Cell–cell adhesion in desmosomes is based on specialized cadherins known as desmogleins and desmocollins ([Chitaev and Troyanovsky, 1997](#)). Unlike AJs, these adhesion receptors are connected within the cell to

Figure 2 Diversity of cell–cell junctions in mouse epithelial cells. Scale bar: 20 μ m.

intermediate filaments. Desmosomes provide additional mechanical resilience to vertebrate epithelial tissues, such as skin (Garrod and Chidgey, 2008).

Signaling or communication junctions include the channel-forming GAP junctions and neuronal synapses, as well as the more transient stimulatory immune synapse, involved in T-cell activation (Rozental *et al.*, 2000). In contrast to tight junctions that block the passage of molecules in the space between neighboring cells, GAP junctions bridge this gap, by forming channels through which small molecules such as ions, amino acids, and secondary messengers can freely pass from one cell to another (Mese *et al.*, 2007). GAP junctions, formed by four-pass transmembrane proteins from the connexin family, are found in many animal tissues, where they serve to coordinate the activity of cells, such as those in the beating heart muscle (Mese *et al.*, 2007).

Neuronal and immune synapses are specialized junctions that combine adhesion and signaling proteins for the localized transfer of information between particular pairs of cells. Though they will not be discussed here, the interested reader is directed to the following reviews (Rozental *et al.*, 2000; Shimizu and Stopfer, 2013).

The Cadherin Family and Diversity of AJs

Interactions between cadherin molecules are mediated through specific cadherin extracellular domains (EC). Structurally, these domains are about 110 amino acids long, and fold into a distinctive immunoglobulin-like shape (Parisini *et al.*, 2007). There are over a hundred proteins in the human genome that contain EC domains, which together comprise the cadherin protein superfamily (Sotomayor *et al.*, 2014). Various cadherins have been shown to be essential for basic processes occurring in cells and tissues, such as neurodevelopment, cell polarization, and migration.

In AJs, however, only a small subset of this diverse family, termed ‘classical cadherins,’ function as adhesion receptors. ‘Classical’ cadherins in humans contain five EC domains, but are best defined by their cytoplasmic tail, which contains a

juxtamembrane binding site for p120-catenin, and a C-terminal binding site for beta-catenin (van Roy and Berx, 2008). Based on conservation of the cytoplasmic tail and overall functional similarity, classical cadherins have also been identified in other organisms such as *Drosophila* and *Caenorhabditis elegans*, despite considerable differences in their extracellular domains (Hill *et al.*, 2001; Oda *et al.*, 1994). While cadherins were found in the pre-metazoan protist *Monosiga brevicollis*, the catenin-binding cytoplasmic tail is believed to be a metazoan development, which may have constituted an important evolutionary turning point in facilitating stable cell–cell adhesions in the earliest metazoans (Abedin and King, 2008; Murray and Zaidel-Bar, 2014).

The human genome encodes 18 classical cadherins (henceforth referred to as cadherins), but only a few of them have been extensively studied. The first cadherin (CDH1) was discovered using antibodies that were capable of inhibiting calcium-dependent cell–cell adhesions, and was thus named cadherin, for ‘Ca²⁺-dependent adhesion’ (Yoshida-Noro *et al.*, 1984). Subsequently, other cadherins were discovered and named after the tissues in which they were found to be prominently expressed. Thus, CDH1 is also known as E (epithelial)-cadherin, CDH2 is N (neuronal)-cadherin, CDH5 is VE (vascular endothelial)-cadherin, CDH3 is P (placental)-cadherin, and CDH15 is M (muscle)-cadherin (Hatta *et al.*, 1985).

As discussed below, the cytoplasmic tails of cadherins associate with a large number of structural and regulatory proteins. Whether the composition of this network of interacting proteins differs, if at all, among the different cadherin subtypes, is currently unknown. However, it is known that different cadherins organize into AJs with distinct structures, as observed with light microscopy. Thus, while E-cadherin forms a continuous adhesion belt along the circumference of the cell in the apical-most region of the lateral membranes (Figure 3(a)), N-cadherin and VE-cadherin commonly form intermittent, zipper-like adhesion structures perpendicular to the line of contact between neighboring cells (Takeichi, 2014).

Importantly, AJ morphology may differ within the same cell type, depending on parameters such as cell density and tension.

Figure 3 Morphological variations of adherens junctions. Illustration of different morphologies of AJs identified in epithelial monolayers and cultures of fibroblasts. (a) E-cadherin (red) and F-actin (green) co-localize to form a continuous adhesion belt along the apical circumference of epithelial cells in a confluent epithelial monolayer. (b) Epithelial cells at the edge of a monolayer forming punctate AJs (white arrows). (c) Streak-like AJs (white arrows) of fibroblasts, with associated actin cables perpendicular to the AJ membrane. Scale bars: 20 μm .

For example, in endothelial cells, stable junctions have been shown to be transformed into focal AJs after treatment with the hormone thrombin (Rabiet *et al.*, 1996); moreover, epithelial cells at the edge of a monolayer exhibit punctate AJs, in contrast to the linear junctions displayed by cells within the sheet (Figure 3(b); Yonemura *et al.*, 1995). Even within the same cell, more than one type of junction can be observed. For example, in both epithelial and endothelial cells, in addition to the more prominent apical junctions, there exists a pool of lateral, spot-like junctions (Takeichi, 2014), which have been observed to translocate along actin filaments in a basal to apical direction, and join the apical junctions (Hong *et al.*, 2010).

Little is known about the mechanism controlling the morphology of a given junction, but it appears to be tightly connected to the F-actin structures associated with it. The lateral adhesion belt in polarized epithelial cells is associated with a thick bundle of F-actin that runs parallel to the membrane, at a short distance from it (Yonemura *et al.*, 1995). Streak-like AJs in fibroblasts and endothelial cells, on the other hand, are associated with stress fibers that approach the membrane at an angle close to perpendicular, and appear to connect to the AJ (Figure 3(c); Noria *et al.*, 1999). Mechanical continuity has also been noted between stress fibers in neighboring cells, mediated by the AJ (Millan *et al.*, 2010).

The Molecular Basis for Cadherin–Cadherin Binding

The extracellular domains of several classical cadherins have been crystallized (Harrison *et al.*, 2011; Shapiro *et al.*, 1995), and based on their solved structures, a model for cadherin–cadherin interactions has emerged (Brasch *et al.*, 2012; Figure 4(a)). Calcium ions bind in between consecutive cadherin domains, and act to rigidify the crescent-shaped extracellular domain and facilitate *trans* interactions. The primary adhesive interaction involves strand swapping between the first cadherin domain (EC1) (closest to the N-terminus) of apposing cadherins. Depending on the particular cadherin subtype, this involves one or two tryptophan residues that insert themselves into a hydrophobic pocket of the apposing cadherin (Brasch *et al.*, 2011; Harrison *et al.*, 2011).

Another type of *trans* interaction, observed in the crystal structure when the tryptophan is mutated, is known as an X-dimer (Harrison *et al.*, 2010). It has been suggested that the X-dimer, which is weaker than the strand-swapped dimer, might represent an intermediate interaction that occurs as the strand-swapped dimer is being assembled or disassembled (Harrison *et al.*, 2010; Hong *et al.*, 2011). The crystal packing also reveals the basis of the *cis* interaction (between cadherins on the same cell), which is mediated by interfaces on EC1 and EC2 (Harrison *et al.*, 2011). Importantly, the *cis* and *trans* interactions occupy different surfaces of EC1, such that a given cadherin can engage in both *cis* and *trans* interactions, and thus create a lattice of tightly packed dimers (Harrison *et al.*, 2011). Molecular dynamics modeling suggests that *trans* dimerization stabilizes cadherin in such a way that *cis* interactions become more probable, and *vice versa*, creating a positive feedback mechanism promoting the growth of a polarized lattice (Wu *et al.*, 2011). Whether cadherin in cells organizes in a manner

similar to that observed in the crystal structure remains unproven. However, super-resolution microscopy has revealed molecular densities at the core of cadherin clusters that are equivalent to the densities expected for the crystal structure packing (Wu *et al.*, 2015).

The Cytoplasmic Plaque

Cadherin's 150 amino acid-long cytoplasmic tail is unstructured on its own, but is stabilized and protected from proteolysis by binding two armadillo repeat proteins from the catenin family of adaptors. P120-catenin (or one of its paralogs: delta-catenin, ARVCF, p0071, and plakophilin) binds at the juxtamembrane region, and beta-catenin (or its close paralog, plakoglobin) binds at the C-terminus of the cytoplasmic tail (Pokutta and Weis, 2007). The binding of p120-catenin not only protects the tail from proteolysis, but also serves to conceal an endocytic signal (Hartsock and Nelson, 2012). Beta-catenin, which was shown to bind to the cadherin tail already in the endoplasmic reticulum (Chen *et al.*, 1999), has many important binding partners, most notably vinculin (Hazan *et al.*, 1997) and its close relative, alpha-catenin (Drees *et al.*, 2005).

In addition to these two armadillo repeat catenins, cadherin cytoplasmic tails have been shown to bind directly with more than a dozen other proteins, some of which (e.g., ankyrin, IQGAP1, and NUMB) are structural proteins and adaptors, whereas others (e.g., RapGEF1, CSK, and Trio) primarily display regulatory functions (Zaidel-Bar, 2013). The binding of these many proteins to the relatively short cadherin tail is mostly mutually exclusive, and dependent on their availability and relative binding affinities.

The binding affinities of the various binding partners can be modulated by post-translational modifications, primarily phosphorylation of specific tyrosine, serine, and threonine residues along the cadherin tail. For example, tyrosine phosphorylation of cadherin creates docking sites for the SH2 domain of the adaptor SHC1 (Xu and Carpenter, 1999) and the PTB domain of the cell polarity protein Numb (Wang *et al.*, 2009). Conversely, phosphorylation of serine residues by casein kinase inhibits the binding of p120 and beta-catenin (Dupre-Crochet *et al.*, 2007). Similar switch-like regulation by post-translational modification governs the interactions between many, if not all, of the plaque proteins at the cytoplasmic face of AJs. In this manner, signaling pathways can rapidly change AJ structure and dynamics.

Dynamic Connections between Cadherin and the Actin Cytoskeleton

Studies in developmental models, as well as cells in cultured epithelial monolayers, provide convincing evidence of a mechanical link between cadherin receptors and the actin cytoskeleton (Borghi *et al.*, 2012; Martin *et al.*, 2009). Indeed, it has been established that lack of anchorage to the actin cytoskeleton renders cadherin clusters unstable, whereas coupling the latter to the cytoskeleton confers stability and directed motility (Hong *et al.*, 2013). Though the molecular

Figure 4 Schematic representation of E-cadherin receptors, interacting with each other via their EC1 domains, and linked to the actin cytoskeleton via α -catenin and vinculin. The encircled cadherin regions (A and B in the box on the left) are illustrated in (a), showing a ball-and-stick model for trans interactions between cadherin extracellular domains; and (b), presenting a network of interactions whereby adhesion receptors (E- or N-Cadherin and Nectin-1) are linked to the actin cytoskeleton, via adaptor proteins.

nature of this connection is still not fully understood, several key proteins have been identified. Foremost amongst the linkers is α -catenin, which contains binding sites for F-actin and for β -catenin (Kobielak and Fuchs, 2004). In *in vitro* biochemical assays, the binding of α -catenin to β -catenin precluded its binding to F-actin (Drees *et al.*, 2005). This finding highlights the fact that conventional biochemical assays fail to simulate the cellular conditions *in vivo*, such as tension applied by actomyosin to the proteins involved. Indeed, a binding assay incorporating forces was able to recapitulate the β -catenin/ α -catenin/F-actin complex (Buckley *et al.*, 2014). Moreover there is substantial evidence that α -catenin at AJs exists in a stretched conformation (Yonemura *et al.*, 2010). The stretching of α -catenin in response to force leads to the unfurling of the protein, and exposes an N-terminal modulatory 1 (M1) domain that binds to vinculin (Ishiyama *et al.*, 2013; Yonemura *et al.*, 2010).

Vinculin at AJs could also conceivably form a link between the cadherin/catenin complex and F-actin. Moreover, α -catenin- and vinculin-dependent recruitment of the vasodilator-stimulated phosphoprotein facilitates actin polymerization at AJs (Vasioukhin *et al.*, 2000). Several other actin-binding proteins, namely, eplin, filamin-A, α -actinin-4, and supervillin, can bind to α -catenin, and thus form a three-component link between cadherin and F-actin (Zaidel-Bar, 2013). Vinculin can also bind to β -catenin directly, and independently of

α -catenin (Peng *et al.*, 2010; Figure 4(b)). Furthermore, cadherin is by no means the only trans-membrane protein at AJs: several other receptors have known connections with F-actin. For example, afadin connects the nectin receptor (Takai and Nakanishi, 2003), and myosin VIIA connects vezatin with F-actin (Kussel-Andermann *et al.*, 2000).

Although the connection with F-actin is by far the most prominent, AJs have also been observed to form connections with the microtubule cytoskeleton and, in some cases, also link with intermediate filaments (Meng and Takeichi, 2009). Anchoring of the minus ends of microtubules to AJs has been described, mediated by dynein or a nezha-plekha7 complex that, in turn, binds to β -catenin or p120-catenin, respectively (Ligon *et al.*, 2001; Meng *et al.*, 2008).

Regulatory Elements of the Cadherin Adhesome

Epithelial cells not only build a complex, structural AJ composed of dozens of proteins, but also engage numerous regulatory networks to enable precise control of AJ assembly, turnover, maintenance and disassembly (Figure 5). The most important regulators of the adhesion plaque include GTPases, activating guanine-nucleotide exchange factors (GEFs) and inhibitory GTPase-activating proteins (GAPs) (Braga and Yap, 2005), kinases, and phosphatases (Bertocchi *et al.*, 2012).

Figure 5 Interplay between regulators at Adherens Junctions. Regulation of cadherin receptors, adaptor proteins and actin regulators is achieved through the action of Rho GTPases, kinases, phosphatases, phospholipids and proteases. Red and blue arrows represent activating and inhibitory interactions, respectively, whereas black arrows represent exocytosis and endocytosis. Representative members from each group of proteins are listed in the box (GEFs, Guanine-nucleotide exchange factors; GAPs, GTPase-activating proteins; Phos, Phosphorylation).

Rho-family GTPases are important regulators of AJs, primarily due to their role in controlling actin polymerization and myosin-driven contractility in cells. The earliest stage of establishment of cell–cell adhesions is driven by high Rac1 activity that stimulates Arp2/3 complex-dependent formation of lamellipodial protrusions, and establishment of contact between cells (Yamada and Nelson, 2007). Following establishment of *de novo* contacts, lamellipodia experience a transient reduction in Rac1 activity, as E-cadherin accumulates and forms nascent AJs. A second wave of elevated RhoA activity

then promotes myosin-based contractility, necessary to expand and complete the formation of a mature junction (Yamada and Nelson, 2007).

Although this type of switch in GTPase signaling may appear conceptually simple, reality is often more complex, to ensure tight spatiotemporal control of GTPase signaling via regulated GEF and GAP activity. For instance, E-cadherin ligation is known to activate phosphatidylinositol 3-kinase (PI 3-kinase) that, in turn, regulates a Rac-GEF called Tiam1 (Nakagawa *et al.*, 2001). Such a signaling cascade may serve to

locally activate Rac1 at sites of cell–cell contact initiation. More recent studies demonstrate novel roles for proteins such as central spindlein, a known cytokinesis regulator, in locally recruiting RhoGEF (ect2) while inhibiting RhoGAP (p190B RhoGAP) localization at AJs, to fine-tune the levels of active RhoA at AJs (Ratheesh *et al.*, 2012).

Besides being regulated by GTPase activity, AJs serve as sites for kinase and phosphatase activity, with at least 21 serine/threonine and tyrosine kinases and 13 phosphatases known to function at AJs (Bertocchi *et al.*, 2012). Phosphorylation or dephosphorylation events can exert one of several possible effects on AJ resident proteins – including stabilizing, destabilizing or altering the binding affinities of protein pairs and complexes (Bertocchi *et al.*, 2012). Although several kinases and phosphatases are known to interact with E-cadherin or the catenins, as determined by immunofluorescence or co-immunoprecipitation, limited knowledge exists concerning the mechanism of localization, and activation of the majority of them.

Elucidating the effects of phosphorylation on AJs has proven to be challenging, due to both positive and negative effects of kinases on AJ assembly, maintenance, and function. For example, increased Src kinase activity in epithelial cells leads to elevated levels of tyrosine phosphorylation, resulting in the subsequent disassembly of AJs (Owens *et al.*, 2000). Although this would suggest negative regulation of AJs by Src kinase, evidence from other studies points to a positive role for Src at cell–cell junctions. Clustering of cadherin molecules during AJ formation triggers Src kinase activity, which is required for further activation of the PI 3-Kinase signaling cascade (Pang *et al.*, 2005). Another member of the Src kinase family, Fyn, has also been positively implicated in the formation of AJs in keratinocytes (Calautti *et al.*, 1998).

Phosphorylation events mediated by tyrosine kinases also contribute to AJ remodeling by regulating E-cadherin endocytosis. Activation of the tyrosine kinase Src in epithelial cells leads to a marked increase in E-cadherin and β -catenin phosphorylation, which in turn stimulates ubiquitination and endocytosis of E-cadherin from AJs (Fujita *et al.*, 2002). Ubiquitination entails the attachment of multiple ubiquitin molecules to a protein, which then induces degradation of the protein by the cell's proteolytic machinery. The E3 ubiquitin ligase Hakai has been found to bind E-cadherin in a tyrosine phosphorylation-dependent manner, and induce ubiquitination and endocytosis as a consequence of binding (Fujita *et al.*, 2002). More recent studies suggest competition in the binding of p120-catenin and Hakai to the juxtamembrane domain of E-cadherin (Hartsock and Nelson, 2012). When bound to the juxtamembrane region of E-cadherin, p120-catenin masks the site for ubiquitination; conversely, Hakai-mediated ubiquitination of the cadherin cytoplasmic tail prevents p120-catenin from binding to and stabilizing E-cadherin at AJs (Hartsock and Nelson, 2012).

Dynamics of Actin at AJs

The dynamics and remodeling of AJs are closely intertwined with those of the actomyosin cytoskeleton; therefore, it is essential to understand the nature of actin dynamics that facilitate AJ remodeling. AJs constitute sites of actin assembly and disassembly, with several nucleation factors known to play

prominent roles in supporting actin polymerization at junctions. Members of the formin family, most notably mammalian Diaphanous 1 (mDia1), have established roles in strengthening cadherin-mediated junctions (Carramusa *et al.*, 2007). The actin-related protein 2/3 (Arp2/3) complex is also known to localize at AJs; inhibiting Arp2/3 complex activity reduces actin nucleation and F-actin content at cadherin adhesions (Kovacs *et al.*, 2002). The Arp2/3 complex itself displays poor intrinsic actin polymerization activity, and is activated by several nucleation promoting factors (NPFs), including cortactin, and members of the WASP (Wiskott-Aldrich Syndrome Protein) and WAVE (WASP-family verprolin homologous protein) families. While several of these NPFs have been found at AJs (Han *et al.*, 2014; Verma *et al.*, 2012), the specific role of each in supporting junctional actin assembly remains unclear. Several other proteins may function as co-factors, to regulate Arp2/3-mediated actin polymerization at AJs. For instance, evidence from *in vitro* studies points to a role for alpha-catenin in inhibiting Arp2/3 activity (Drees *et al.*, 2005), while a more recent study demonstrates a role for alpha-actinin-4 in supporting Arp2/3-dependent actin assembly at cell–cell junctions (Tang and Brieher, 2012).

In addition to direct regulation of actin nucleation at AJs, several proteins contribute to homeostasis of actin filaments at AJs at a post-nucleation stage (Chesarone and Goode, 2009). Depletion of the pointed-end capping protein Tropomodulin-3 (TMOD3) is known to destabilize cell–cell adhesion, due to loss of F-actin along the lateral membranes of polarized epithelial cells (Weber *et al.*, 2007). Evidence from *in vivo* studies also demonstrates a role for tropomodulins in protecting actin filaments that are recruited by alpha-catenin during epithelial morphogenesis in the *C. elegans* embryo (Cox-Paulson *et al.*, 2012). Tropomyosins – integral components of actin filaments – also contribute to stabilization of F-actin at cell–cell junctions, and are essential for maintenance of proper cell shape *in vitro* and *in vivo* (Temm-Grove *et al.*, 1998). Conversely, proteins such as gelsolin that possess potent actin severing properties also modulate actin dynamics at AJs. Phosphoinositide signaling regulates activity of gelsolin that, in turn, contributes to regulation of adhesion strength at N-cadherin-mediated cell–cell junctions (El Sayegh *et al.*, 2007).

Cadherin and Embryonic Development

Cell–cell adhesion plays a critical role in embryonic development, beginning as early as compaction at the eight-cell stage in the developmental timeline of vertebrate embryos. Compaction marks the first differentiation event during development, and requires E-cadherin-mediated cell adhesion to coordinate blastocyst formation from an embryo composed of eight spherical blastomeres. Deletion of the *CDH1* gene in mouse embryos, or treatment with function-blocking E-cadherin antibodies, leads to compaction defects and nonviable embryos (Larue *et al.*, 1994). More recently, elegant experiments using live-embryo imaging demonstrated the extension of E-cadherin-dependent filopodia by blastomeres onto their neighboring cells (Fierro-Gonzalez *et al.*, 2013). Formation of such filopodia is tightly coordinated with cell shape changes, and facilitates

tension generation that helps brings cells closer together, to undergo compaction (Fierro-Gonzalez *et al.*, 2013).

Besides the expression of E-cadherin, several other types of cadherins are expressed in a tissue-specific manner during the course of development. Tissue-specific expression patterns of cadherins facilitate ‘cell sorting,’ a phenomenon that has been identified both *in vivo* and in tissue culture systems, and is based on their differential affinity to other cadherins (Duguay *et al.*, 2003). N-cadherin, for example, forms homodimers with higher affinity than those formed with E-cadherin, so a mixture of cells expressing either will tend to segregate into an inner cluster of N-cadherin expressing cells surrounded by E-cadherin expressing cells (Foty and Steinberg, 2005). Cell sorting mediated by expression and homophilic ligation of compatible cadherin subtypes enables the demarcation of cell types into distinct tissues during embryogenesis. For instance, during oogenesis in *Drosophila*, oocytes localize at the posterior end of the follicle, due to higher levels of expression of DE-cadherin in the posterior follicle cell that favors oocyte-follicle cell interactions (Godt and Tepass, 1998).

However, there also occurs during development the process of ‘cadherin switching,’ which leads to changes in expression from one cadherin type to another. Primary neurulation in chick embryos is associated with a switch in expression from E-cadherin to N-cadherin, to enable formation of a neural tube from a neural plate, and distinguish the neural tube from epidermal cells (Hatta and Takeichi, 1986). A shift towards N-cadherin expression provides neural plate cells with the ability to delaminate and migrate, a phenomenon known as epithelial-to-mesenchymal transition (EMT). Gastrulation during *Drosophila* development also involves a transition from DE-cadherin to DN-cadherin expression in developing mesodermal tissue, accompanied by EMT (Oda *et al.*, 1998).

AJs are intimately associated with the actomyosin cytoskeleton via several intermediate proteins, and the importance of this connection is evident in a variety of processes throughout the course of morphogenesis. Germband extension in *Drosophila* results in narrowing of the embryo along the dorsal-ventral axis, concomitant with elongation along the anterior-posterior axis (Bertet *et al.*, 2004). This process is driven by the intercalation of ectodermal cells that occurs as a result of AJ remodeling and actomyosin contractility (Rauzi *et al.*, 2010). The distributions of DE-cadherin and Myosin-II are planar polarized and complementary to one another, an arrangement that is essential for proper intercalation. The planar-polarized distribution of DE-cadherin orients the flow of apical actomyosin networks toward junctions with low DE-cadherin and higher myosin-II levels, thus causing these junctions to contract preferentially, to enable cell intercalation (Rauzi *et al.*, 2010). Several other processes such as apical constriction during gastrulation also require coordination between junction remodeling and contractions of the actomyosin network, thus illustrating the prominent role played by AJs during morphogenesis (Mason *et al.*, 2013).

AJs in Disease

Cancer metastasis is a complex process, often involving loss of cell–cell adhesion, increased migration, and invasion of cancer

cells into distant tissues, followed by colonization and formation of secondary tumors. By virtue of facilitating cell–cell adhesion via formation of AJs, loss of E-cadherin function appears to promote metastasis and invasiveness in human epithelial tumors, due to weaker contacts between neighboring cells. Down-regulation of E-cadherin expression is often correlated with highly metastatic cancers, and associated with adverse patient outcomes (Asgeirsson *et al.*, 2000). However, it is important to note that loss of E-cadherin, in and of itself, is not sufficient to drive cancer or metastasis, but rather accompanies cellular transformation that involves many other changes (Shamir *et al.*, 2014).

In the vast majority of primary cancers affecting multiple organ types, transcriptional down-regulation of E-cadherin expression via hyper-methylation of the *CDH1* promoter contributes to loss of cell–cell adhesion (Bex and van Roy, 2009). Excessive methylation of CpG islands in the promoter region of E-cadherin triggers histone 3 (H3) deacetylation, which shuts down transcription (Chen *et al.*, 2003). In addition to promoter hyper-methylation, the binding of transcription factors such as Snail, Slug and Twist to E-box sequences within the *CDH1* promoter are also known to suppress transcription and promote tumor invasion (Batlle *et al.*, 2000). Expression of these transcription factors is associated with EMT and increased migratory potential that, in turn, are commonly associated with cancer metastasis. Next-generation sequencing techniques have also demonstrated a role for inactivating mutations in the *CDH1* gene as a trigger for promotion of weaker cell adhesion and metastasis (Bex *et al.*, 1996). However, the effects of such mutations are limited to breast and gastric cancers (Soares *et al.*, 1997).

It is interesting to note that reduced expression of E-cadherin in tumor cells is frequently associated with higher levels of N-cadherin expression, an adhesion receptor predominantly found in neurons and mesenchymal cells. While this process of ‘cadherin switching’ occurs during developmental processes such as gastrulation, it is likely that increased N-cadherin expression might contribute to acquisition of migratory phenotypes among cancer cells, and hence promote the spread of tumors.

The function of E-cadherin in facilitating cell adhesion is intimately associated with its ability to bind to members of the catenin family via its cytoplasmic tail region. It is thus not surprising that changes in catenin expression, in particular alpha-catenin, closely mirror those of E-cadherin in a wide range of epithelial cancers (Zhou *et al.*, 2005). Although alpha-catenin levels can be reduced to as much as 40–80% in a variety of cancers (Zhou *et al.*, 2005), little is known about the mechanisms involved in down-regulation of its expression. While loss-of-function mutations in the alpha-catenin gene have been identified in *in vitro* culture systems for tumor cells, limited evidence exists that would clarify their roles *in vivo* in primary and secondary tumor formation.

Although E-cadherin and the catenins have been the focus of intensive research for their causal roles in cancer metastasis, it bears remembering that other human diseases also arise out of defects in function of nonclassical or desmosomal cadherins. Desmosomal cadherins have been predominantly implicated in diseases affecting skin and hair follicles, while defects in nonclassical cadherins often result in neurosensory complications that manifest as retinal or inner ear diseases.

For instance, the nonclassical cadherins, Cadherin-23 and Protocadherin-15, which form the tip link in hair cells in the inner ear, are mutated in Usher syndrome (USH), resulting in blindness and deafness (El-Amraoui and Petit, 2005). We refer readers to several reviews that further highlight the involvement of desmosomal and nonclassical cadherins in disease development and progression in humans (Al-Jassar *et al.*, 2013; El-Amraoui and Petit, 2005).

Concluding Comments

In this article, we have discussed, with some historical perspective, the structure, functions, and diversity of intercellular junctions, and their involvement in major processes in metazoan organisms, in health and disease. We have addressed the critical roles of these adhesions in the evolution of multicellularity, and focused on both their cardinal mechanical role in supporting tissue scaffolding and morphogenesis, and their involvement in intercellular communication, critical for body homeostasis. Zooming in on the nanostructure of cell–cell adhesions, we discussed the multimolecular networks that, in concert, perform the scaffolding, sensing, and signaling tasks of the different adhesion sites. In this context, much attention is focused on the roles of the cytoskeleton in physically supporting cell adhesions and in participating in local mechanosensing, and the involvement of a wide variety of adhesion-associated enzymes (e.g., kinases, phosphatases, and their regulators) in the signaling process. It is noteworthy that recent studies, based on advanced and powerful molecular genetic and imaging technologies, combined with *in vivo* and *ex vivo* approaches, provide a wealth of information on the molecular components of the various adhesion systems, and their individual contributions to the functions of these sites. These studies also make it increasingly clear that the next major challenge is to address junction biology via integrative, ‘systems level’ approaches, whereby the diverse functions of these cellular structures are evaluated in the context of networking of their multiple constituents.

Introduction

Connective tissue cells and matrices are distributed throughout the bodies of mammals and other metazoans and play key roles in organizing and supporting tissues and organs. Connective tissue matrices provide continuity with other cells and transduce chemical and physical stimuli that regulate cell activity. While extracellular matrices may appear to be inert, many matrices are highly dynamic and undergo remodeling as a result of cell-mediated synthesis and remodeling. The remodeling of the connective tissue matrix is essential for preserving healthy tissues and organs throughout life. Disturbances of matrix remodeling are involved in a vast array of inflammatory, neoplastic, and atrophic diseases (McCarty *et al.*, 2012; Hopps and Caimi, 2012; Eckhouse and Spinale, 2011; Lu *et al.*, 2011) which arise in part from the diverse structure and function of matrix molecules and the complex behavior of connective tissue cells that are responsible for the remodeling of the matrix.

When seen from the top, a cell that is deposited from a three-dimensional suspension onto a flat surface can bind and spread along the surface in a manner that can closely resemble that of a liquid drop wetting a surface (Sackmann and Bruinsma, 2002) or a phospholipid vesicle flattening on a surface to which it adheres (Sackmann and Smith, 2014; Bell and Torney, 1985). In all three cases objects that are approximately spherical in three-dimensional suspension become flattened as they adhere to the surface, but eventually reach a finite area that is determined by a balance of forces that reach equilibrium or at least a steady state when the adhesive energy at the interface becomes comparable to the mechanical work required to deform a viscoelastic cell or a lipid droplet with surface tension (Sackmann and Smith, 2014). In some

cases of single cells or even spherical aggregates of cells adhering to appropriate surfaces, the rates and extents to which the cells adhere and spread are similar to those of viscoelastic liquid drops wetting a surface (Doeznan *et al.*, 2011), but there are also many structural and thermodynamic differences between a cell or a cell aggregate and a simple liquid drop (Beaune *et al.*, 2014). One important difference is that even when cells adhere to molecularly flat surfaces the adhesive interface is not flat and continuous but rather is formed by small discrete regions of the basal cell membrane that may be in close contact with the substrate, leaving the rest of the cell membrane unbound to the substrate and often fluctuating distances of several hundred nanometers above the surface, as has been well documented by reflection interference microscopy (Curtis, 1964), and other methods. A second important difference between microscopic cells and macroscopic liquid drops is that the cell membrane is small and soft enough to undergo significant thermal fluctuations as well as molecular motor-driven nonthermal motions whereas a macroscopic liquid drop surface is usually too large to be governed by factors other than its surface tension. A further essential difference is that the chemistry of drops wetting the surface is often driven by a uniform set of interactions between molecular structures that are very closely spaced, and can often be reasonably modeled as continuous interfaces, whereas cell–substrate or cell–matrix interactions are dictated largely by highly specific interactions between a well-defined set of transmembrane proteins and their unique set of ligands, as discussed in examples cited below, and these specific receptor–ligand bonds are often spaced many nanometers apart even in those regions of the cell membrane that make close contact with the surface (Geiger *et al.*, 2009). A summary of the opposing interactions that control the cell–substrate interface is shown in Figure 1.

Figure 1 Summary of biochemical and mechanical effects mediating cell adhesion to surfaces. Reproduced with permission from Sackmann, E., Bruinsma, R.F., 2002. Cell adhesion as wetting transition? *ChemPhysChem* 3, 262–269.

Early Studies of Cell Adhesion

Pioneering studies of cell adhesion emphasized the role of substrate surface chemistry or topography on the ability of cells to adhere to them. Many early studies used hydrogels rather than glass or plastic surfaces as the substrates because the hydrogels formed either from native or synthetic biopolymers are better mimics of the extracellular matrix *in vivo*. Such studies, employing human tumor-derived HeLa cells and primary human fibroblasts established that these mammalian cells would not bind to alginate, agar, or silica gels unless they had been treated with human serum, but they bound to gels formed by collagen 1 or fibrin in the absence of serum, and that fibrinogen also was sufficient to transform alginate, agar, or silicate gels from nonadhesive to adhesive (Weiss, 1959). Such studies suggested that specific interactions between cell surface molecules and their ligands on the substrate were important for mediating adhesion. Later, studies showed that coating nonadhesive surfaces with polyvalent cations such as protamine (Steinhardt *et al.*, 1971) or polylysine (Maceira-Coelho and Avrameas, 1972; Mazia *et al.*, 1975) strongly facilitated attachment of cells to surfaces, by mechanisms that depended on electrostatic interaction between the positively charged surface and negatively charged polymers, such as those of the glycocalyx, that extend from the cell membrane.

Specific versus Generic Attractive and Repulsive Interactions

A great deal has been learned about the molecular biology of transmembrane adhesion receptors such as integrins, selectins, CD44, ICAM 1, and other protein complexes along with the biochemistry of their interactions with extracellular proteins such as fibronectin, collagen, fibrin, hyaluronic acid, chondroitins, and many other ligands (Heisenberg and Fassler, 2012). The fact that cell adhesion on specific surfaces can depend essentially on docking to ligands that contain the sequence RGD (arginine-glycine-aspartate) (Ruoslahti and Pierschbacher, 1987) might suggest that cell adhesion is entirely determined by the functions of these proteins and the distribution of their ligands, both of which are strictly regulated by the genetics and signaling mechanisms of the cells that produce them. In such a case resemblance of cell adhesion and surface wetting would appear to be coincidental, but there are other molecular and physical features of cell adhesion that suggest that much more is to be learned about the physics of cell-matrix interactions to accompany the wealth of information about its biochemistry.

Even when cell adhesion requires the function of a specific transmembrane protein such as an integrin, and cells detach immediately when this protein is degraded, the interface between the cell and substrate is defined by many other macromolecules at the cell surface and the substrate that modify the function of the essential adhesion protein or the morphology of the cell. The affinity and dynamics of the adhesive protein-substrate interaction can determine the strength of the binding but not necessarily the morphology of the cell or the stability of the interface. For example, many cell membranes also express membrane proteins with very large

polypeptide or carbohydrate chains that extend hundreds of nanometers or even several microns away from the lipid bilayer to form a so-called glycocalyx or pericellular matrix, and similar glycosaminoglycans form much of the extracellular matrix *in vivo* (Fotia *et al.*, 2013). The pericellular matrix is in some sense anti-adhesive because in order for the cell membrane to make close contact with a flat substrate the pericellular matrix molecules must be compressed to allow the adhesive transmembrane protein (integrin, selectin, etc.) to reach its matrix target. Recent studies have shown that the entropic cost of compressing the pericellular matrix as well as the osmotic pressure produced as the charged polyelectrolytes in the glycocalyx become concentrated along with their counterions can alter the nature of the bond between an integrin and its ligand. These effects can either stabilize the adhesion site or destabilize it depending on whether the integrin-ligand interaction contains slip or catch bonds (Fotia *et al.*, 2013; Paszek *et al.*, 2014). A further complication in cell adhesion is that the bound interface is not a passive material but rather, as adhesion proteins bind their matrix ligands, factors bound to the intracellular domains of these proteins stimulate the assembly of actin-based cytoskeletal fibers, activate myosin motors through small GTPase signals, activate enzymes that synthesize polyphosphoinositides at the site of the surface, and thereby enhance membrane fluctuations and contractile forces specifically at the site where transmembrane proteins engage the matrix (Opas, 1995; Harris *et al.*, 1980). The work done at these adhesion sites has a strong influence on the nature of the adhesive substrate that can in some cases resemble changes in surface tension at the surface of liquid drops, but that arises from different molecular mechanisms.

Stiffness, Spacing, and Curvature

The adhesive interface between cells and surfaces is influenced by the physical properties of the interface as much as by the chemical interactions between cells and substrates. Much recent work has documented the importance of physical features such as surface topography and elastic modulus on the ability of cells to bind and spread on mechanically different surfaces that have the same surface chemistry and density of ligands for transmembrane receptors. The stiffness of the planar surface of the three-dimensional matrix has a very strong affect on the adhesive interface, extent of cell spreading, and many aspects of cells, including their rate of motility, proliferation, and differentiation. Usually more rigid surfaces promote greater rates of cell spreading and larger interfaces, and promote cell proliferation, but there are significant exceptions especially in cell types such as central nervous system neurons that are derived from very soft tissues and extend their adhesive interfaces more robustly in soft materials that mimic the elastic modulus of the brain (Discher *et al.*, 2005). Surface topography can also strongly affect cell adhesion (Kim *et al.*, 2012). For example, the spacing of ligands for integrins determines both the initial attachment and eventual morphology of the adherent cell. If integrin ligands are spaced in ordered arrays at distances below a critical value (approximately 50 nm), cells adhere to such surfaces as they do on surfaces of contiguous ligand distribution, but if the ligand spacing is greater, cells

can initially attach, but their long-term spreading and eventual phenotype can vary widely, and can lead to cell detachment and death if the adhesive spacing is too large (Cavalcanti-Adam *et al.*, 2006). Curvature can also be a strong determinant of cell adhesion in a highly celltype-specific manner. For example, when non-transformed IAR-2 epithelial cells were cultured on 32- μ m-diameter glass fibers, they oriented their actin-based cytoskeletal fibers and fibronectin-based adhesion sites longitudinally along the axis of the fibers but the majority of ras-transformed cells from the same source oriented their actin fibers and adhesion sites transversely around the fiber (Levina *et al.*, 1996). Similarly, neurons extend processes and move along the axis of fibers in a fiber diameter and stiffness-dependent manner with optimal movement at curvatures in the range of axons (Smeal *et al.*, 2005). Even on flat substrates, curved edges of patterned adhesive protein influence the formation of lamellipodia and cytoskeletal assembly (James *et al.*, 2008). Here the mechanics of membrane and cytoskeletal bending rather than strength of adhesion receptors appear to dominate the morphology of the adhesive interface (Biton and Safran, 2009).

How Extracellular Signals Alter Adhesion to Matrix

Adhesive cell-matrix interactions are governed primarily by the activity of integrins, heterodimeric proteins, composed of α and β subunits that connect the cytoskeleton to components of the extracellular matrix. The activity of integrins is determined by the affinity with which they bind their ligands, and the strength of adhesion between a cell and the matrix is further determined by the number of engaged integrins on the cell surface. The activity of integrins responds to signaling pathways controlled by membrane and cytosolic signaling proteins (inside-out signaling), and integrins transmit information from the outside of cells in response to binding ligands (outside-in signaling) (Pouwels *et al.*, 2012). Integrins can exist in high- or low-affinity states for their extracellular ligands, and the inability to switch affinity states results in a range of diseases. This section will consider control of integrin function by extracellular signals. *In vivo*, inside-out, and outside-in signaling are difficult to separate because a cell's responses to its physical and chemical environment are mutually dependent, dynamic, and iterative.

Different combinations of the 18 α and eight β subunits result in 24 different integrins with binding specificities for different extracellular ligands such as collagen, laminin, fibronectin, and fibrinogen. Integrin expression is cell type specific resulting in cell type-specific interactions with matrix. Both subunits have single transmembrane domains and highly glycosylated extracellular domains that bind the ligand. The short intracellular domain of the β subunits interacts with a collection of proteins, some of which, like talin, filamin, and α -actinin, link the β subunit to the actin cytoskeleton. Proteins that interact with the C-termini of α subunits are less well understood, but include SHARPIN, MDGI (mammary-derived growth inhibitor), and RhoGAPs. The α and β subunit C-termini bind common partners and subunit-specific cytoplasmic partners with affinities that depend on the specific subunit. Additionally, talin and the Itg β subunit form the

nidus for aggregation of 50 or more proteins with structural and signaling functions, forming focal adhesions.

Talin appears to be the central protein in signaling from the cell to integrins and signaling from the matrix via integrins to the cell. Talin1 and Talin2 are related genes coding for similar proteins with similar functions and different patterns of expression. Talin is primarily present in the cytosol in an auto-inhibited conformation in which the rod domain blocks the F2-F3 regions of the head domain preventing membrane association (Das *et al.*, 2014; Song *et al.*, 2012). In response to extracellular signals that may include toll-like receptors, G protein-coupled receptors, receptor tyrosine kinases, and cytokine receptors, and activation of intracellular cell signaling pathways that can involve PIP₂, PKC α , and particularly Rap1, talin localizes to the plasma membrane at the site of integrin C-termini (Chung *et al.*, 2014). Since both Rap1 and PI3-kinase are downstream of cAMP (cyclic adenosine monophosphate) signaling, numerous extracellular signals are capable of activating this pathway. The Rap1 effector, RIAM interacts directly with talin via a high-affinity site and recruits it to the plasma membrane (Chang *et al.*, 2014; Calderwood *et al.*, 2013). In platelets, talin and kindlin are bound by ADAP (adhesion and degranulation promoting adapter protein), a membrane-associated scaffolding protein that localizes them near the β integrin C-terminus (Kasirer-Friede *et al.*, 2014). Kindlin then binds to the β integrin-talin complex reinforcing it. Talin exists as a dimer and so can initiate integrin clustering (Das *et al.*, 2014).

In the absence of stimulation, integrins exist in low-affinity, folded states where their affinity for ligands is low. Binding of the talin head domain to the C-terminus of β subunits induces a conformational change in the β subunit that appears to originate with separation of the α and β transmembrane domains and straightening of the β extracellular domain resulting in changes in the conformation of the N-terminus and an intermediate affinity binding state. A high-affinity state is produced by traction force on the integrin complex (Schurpf and Springer, 2011). Further adhesion to matrix results from integrin clustering (above) and traction as well as the binding of additional proteins to adhesion complexes.

Following initial or nascent complex formation, additional proteins such as vinculin and paxillin bind to the complex with increased binding in the presence of mechanical stress (Oakes and Gardel, 2014). Many of the proteins that join adhesion complexes following their initial formation are signaling proteins such as FAK, other Src family kinases, phosphatases, scaffolding proteins such as zyxin and p130CAS, motor proteins such as non-muscle myosins, or actin polymerizing complexes such as Arp2/3 or formins. Many of the proteins in the complex are phospho-acceptors (targets of kinases and phosphatases) or kinases and phosphatases themselves. Adhesion complexes both generate signals and respond to a range of signals from the cell, many originating as extracellular signals. The scenario described above is generalized and simplified, but is consistent with the current literature (Das *et al.*, 2014; Schurpf and Springer, 2011; Delon and Brown, 2007). The details of what proteins bind and in what order will evolve with new experimental systems and approaches, and may also depend on the cell type and specific integrins.

Cell Adhesions and Matrix Molecules in Connective Tissue Function

The synthesis and degradation of the extracellular matrix are coordinated to maintain connective tissue homeostasis (Hinz, 2013). Collagen is the most abundant molecule of mammals (Perez-Tamayo, 1978) and exerts dominant influences on the chemical and mechanical properties of connective tissues. The remodeling of collagen requires the synthesis of new molecules and the degradation of worn-out or effete molecules by collagenolysis. Because collagen is highly insoluble, specialized types of degradative systems have evolved to enable collagenolysis, such as the matrix metalloproteinase family of endopeptidases (Steffensen *et al.*, 2001; Murphy and Nagase, 2008). Another important but less well-understood system for collagen degradation is intracellular collagen degradation by phagocytic fibroblasts, which is critical for physiological matrix remodeling and wound healing (Everts *et al.*, 1996; Ten Cate, 1972). In collagen phagocytosis, fibroblasts initially adhere to collagen, followed by partial digestion of collagen fibrils extracellularly (Lee *et al.*, 2006); shorter segments are then internalized and digested intracellularly by lysosomal cathepsins (Burleigh *et al.*, 1974; Song *et al.*, 2006; Van Noorden and Everts, 1991; Nallaseeth *et al.*, 2013). In tissues with rapid matrix remodeling including the involuting uterus (Dyer and Peppler, 1977), periodontal tissues (Ten Cate, 1972), and healing wounds (McGaw and Ten Cate, 1983), collagen turnover is directly related to the volume density of collagen fibrils in phagosomes within fibroblasts (Everts *et al.*, 1996), indicating that phagocytosis is critical for collagen turnover (Everts *et al.*, 1996, 1995).

Remodeling of the extracellular matrix and the maintenance of connective tissue structures is highly dependent on the attachment of cells to matrix proteins. These attachments are important not just for the preservation of cell vitality and proliferation, but also for physiological cell migration and the degradation of collagen, which is the most abundant matrix protein of mammalian connective tissues (Perez-Tamayo, 1978). The extracellular matrix exerts multiple influences on tissue physiology, including dominant contributions to mechanical properties, reactivity to environmental changes, and the ability to regulate signaling processes. In particular, the ability of matrix interactions to influence tissue physiology is dependent on cell adhesions to the matrix, which can influence the macromolecular architecture of secreted matrix components. Conversely, matrix molecules can influence the organization of cell adhesions, which in turn propagate signals into cells (Kim *et al.*, 2012). An important element of this reciprocal signaling system is the mechanical continuity between the extracellular matrix, cell surface adhesion receptors such as integrins, and the cytoskeleton (Ingber, 1997; Wang *et al.*, 1993). The continuity of these structures is an important structural element that enables chemical and mechanical signaling, which together regulate many processes that affect matrix structure and function. At specialized attachment plaques known as focal adhesions, integrins, actin filaments, and a large group of actin-binding proteins are assembled into structures that mediate cell attachment and signal transduction (Schoenwaelder and Burridge, 1999).

Cell attachment to matrix proteins is mediated by a large variety of adhesion molecules, including integrins

(Covell, 1990). Integrins bind extracellular matrix proteins with considerable ligand specificity. For example, collagen binds preferentially to the $\alpha_2\beta_1$, $\alpha_1\beta_1$, $\alpha_{10}\beta_1$, or $\alpha_{11}\beta_1$ integrins. In connective tissues in which there are abundant collagen fibers, mechanical forces often play a central role in tissue function, such as the cardiac interstitium. In these tissues, the integrins expressed by resident myocytes and fibroblasts provide bidirectional signaling between cells and fibrillar extracellular matrix proteins. These types of signaling processes are common in many types of cells but are particularly evident in tissues where high-amplitude physical forces are applied (Hierck *et al.*, 1996). Force-related adhesion signals can promote rapid matrix remodeling (Schorb *et al.*, 1994) and abundant collagen turnover. Because integrins physically associate with signaling and actin-binding proteins such as talin, integrins provide adhesive and mechanosensory functions (Katsumi *et al.*, 2004) through focal adhesions.

Focal adhesions are actin-enriched adhesive domains found in many cultured cells including fibroblasts, endothelial cells, synovial cells, and chondrocytes (Critchley, 2000). Focal adhesions form at sites of clustered integrin receptors bound to extracellular matrix ligands. They are dynamic structures that undergo distinct maturational steps with distinct molecular composition (Wehrle-Haller and Imhof, 2002). Once thought to be strictly structural adhesive complexes, focal adhesions are now recognized for their role in signal transduction (Burridge and Chrzanowska-Wodnicka, 1996; Wehrle-Haller and Imhof, 2002). Over 50 signaling molecules are detected in nascent adhesions (Aplin and Juliano, 1999; Garrington and Johnson, 1999) one of which is the focal adhesion kinase, a 125 kDa tyrosine kinase that plays important roles in cell adhesion, contractility, migration, and signaling (Schaller, 2010). The importance of the focal adhesion kinase in adhesion-related functions is demonstrated by the behavior of focal adhesion null fibroblasts, which are highly adherent and form large, stable adhesions (Ilic *et al.*, 1995). Integrin ligation of matrix molecules like collagen or fibronectin induces auto-phosphorylation of the focal adhesion kinase, which creates binding sites and enables recruitment of other signaling proteins at focal adhesions.

Role of Cell-Matrix Adhesions in Pathological Processes: Fibrosis

As extracellular matrices in many tissues undergo continuous turnover and replacement during growth, development, and function in adults, a failure to control matrix dynamics can lead to excessive and inappropriate matrix formation or tissue destruction. These disorders of matrix biology are hallmarks of various neoplastic and fibrotic diseases (e.g., congestive heart failure (Shah and Mann, 2011)) and high prevalence inflammatory diseases such as arthritis and periodontal diseases. Cells in mechanically active environments including joint, myocardium, lung, gastrointestinal tract, and periodontium are subjected to high-amplitude exogenous forces. Under conditions of chronic high load, mechanically induced cell death can promote fibrosis, cell death, and loss of organ and tissue function as is seen in arthritis, heart failure, and periodontal diseases.

Commonly used drugs for management of hypertension, epilepsy, and organ transplantation (e.g., nifedipine, dilantin, cyclosporin A, respectively) disrupt calcium signaling and inhibit the normal adhesion of cells to matrix molecules. This disruption leads to blockade of intracellular collagen degradation in fibroblasts (McCulloch, 2004) and to significant fibrous overgrowth of periodontal tissues, a major clinical management problem in periodontology. There is no effective treatment for these disorders and there is significant morbidity (Mavrogiannis *et al.*, 2006). Disruption of cell–matrix adhesions in collagen phagocytosis is thus a critical pathway in maintaining the health and function of oral connective tissues.

In several cardiac diseases such as pressure overload, diabetic cardiomyopathy, and myocardial infarction, fibrosis is a common disorder of myocardial extracellular matrix structure and function. The clinical significance of fibrosis is that accumulation of disorganized fibrillar collagen in the cardiac interstitium can inhibit diastolic and systolic function. Fibrosis is mediated by several different cellular and extracellular processes including disruptions of fibroblast differentiation, perturbations of posttranslational processing and assembly of matrix molecules, and inappropriately organized matrix degradation by proteases and intracellular digestion. The enlargement of transformed fibroblast and myofibroblast populations in the diseased cardiac interstitium plays a critical role in the disorganized matrix remodeling that occurs after pressure overload or diabetes because these cells do not process and remodel interstitial collagen in a physiological fashion.

In addition to alterations of matrix structure and function as a result of fibrotic processes, the attachment of cells to extracellular matrix proteins can also regulate pro-inflammatory signaling that leads to matrix destruction. Interleukin-1 is a potent, pro-inflammatory cytokine that contributes to inflammatory tissue injury in lung fibrosis, arthritis, and periodontitis. In fibroblasts and chondrocytes, IL-1-induced signaling requires the formation of focal adhesions and the tight adaptation of cells to the underlying matrix (Arora *et al.*, 1995). Focal adhesions in these cells are enriched with IL-1 signaling receptors, and possibly other critical signaling elements of the IL-1 signaling pathway, such as SHP-2 and PTP α , protein tyrosine phosphatases that are found in focal adhesions and that play critical roles in IL-1-induced focal adhesion maturation, function, and signaling to enable matrix degradation (Herrera Abreu *et al.*, 2006).

Role of Cell–Matrix Adhesions in Pathological Processes: Platelets and Thrombosis

Platelet activation provides useful examples of physiology and pathophysiology in extracellular signaling and integrin activation. Reduced platelet activation results in inappropriate bleeding, and increased platelet activation results in thrombus formation and ischemic injury to organs, commonly the heart (myocardial infarction), brain (strokes), limbs, and intestines. Platelets express an integrin, $\alpha\text{IIb}/\beta 3$, that is a receptor for fibrinogen, the GPIb-IX-V complex that is a receptor for von Willebrand factor, and multiple G protein-coupled receptors for compounds including thrombin, adenosine diphosphate (ADP), and thromboxane A₂ (TxA₂), all receptors

that participate in platelet activation (Shattil *et al.*, 1998). Platelets are maintained in an inactive state in the circulation by intact endothelium, endothelial production of PGI₂, NO, and an ADP degrading enzyme (ADP activates platelets), along with the absence of platelet activators. Activated platelets are characterized by high-affinity binding of fibrinogen by $\alpha\text{IIb}/\beta 3$ with $\alpha\text{IIb}/\beta 3$ clustering and link age of multiple platelets through fibrin polymers, cytoskeletal rearrangements so that platelets spread, and degranulate to release substances that include ADP and von Willebrand factor, and increase surface expression of $\alpha\text{IIb}/\beta 3$. Platelets are normally activated in the presence of tissue injury with endothelial disruption and loss of activation inhibitors, exposure of the von Willebrand factor that binds its receptor and slows circulating platelets, and release of ADP, thrombin, and TxA₂ as well as binding of fibrinogen or collagen to $\alpha\text{IIb}/\beta 3$. However, binding of fibrinogen and collagen to $\alpha\text{IIb}/\beta 3$ alone is insufficient to activate platelets and lead to activation of $\alpha\text{IIb}/\beta 3$ with high-affinity binding of fibrinogen. Full platelet activation requires collaboration of the GPIb-IX-V complex and G protein-coupled receptors such as those for ADP. Mutations in the GPIb-IX-V complex, G protein-coupled receptors, or their signaling pathways result in platelet abnormalities with medical importance (Van Geet *et al.*, 2009). For example, reduced expression of von Willebrand factor (congenital or acquired), or loss of function mutations in its receptor, the GPIb-IX-V complex (Bernard–Soulier syndrome or Velocardiofacial syndrome (VCFS), all of which reduce platelet–matrix binding lead to increased bleeding risk.

Conclusion

Cell adhesion to extracellular matrices is an important regulator of cell function. Changes in the chemical or physical features of the matrix can have as great an impact on cell function as do biochemically and genetically controlled changes in the expression of specific proteins by which cells bind their matrix. In many cases selectivity and affinity of specific cells to specific matrices or substrates depends on expression of a small number of transmembrane adhesion proteins and their matrix ligands but many other more generic effects such as surface topography, ligand spacing, electrostatic charge, and mechanical compliance of the matrix also have significant effects on cell adhesion that can lead to changes during normal tissue development or pathology.

Introduction

Defects in planar cell polarity (PCP) result in a range of developmental anomalies (birth defects) and diseases including neural tube closure defects (reviewed in [Simons and Mlodzik, 2008](#); [Copp and Greene, 2009](#)), polycystic kidneys (reviewed in [Simons and Walz, 2006](#); [Wallingford, 2006](#); [Wang and Nathans, 2007](#); [Simons and Mlodzik, 2008](#)), conotruncal heart defects ([Garriock et al., 2005](#); [Phillips et al., 2005, 2007](#); [Henderson et al., 2006](#)), deafness ([Curtin et al., 2003](#); [Montcouquiol et al., 2003, 2006](#); [Lu et al., 2004](#); [Davies et al., 2005](#); [Wang et al., 2005, 2006a,c](#); [Deans et al., 2007](#); [Qian et al., 2007](#); [Jones et al., 2008](#)), and situs inversus (reviewed in [Santos and Reiter, 2010](#)). PCP polarizes skin and hair ([Guo et al., 2004](#); [Wang et al., 2006b,c](#); [Devenport and Fuchs, 2008](#)), and is also believed to underlie directed migration during wound healing ([Lee and Adler, 2004](#); [Caddy et al., 2010](#)) and invasion and metastasis of malignant cells ([Weeraratna et al., 2002](#); [Lee et al., 2004](#); [Katoh, 2005](#); [Coyle et al., 2008](#); [Kuriyama and Mayor, 2008](#)). Despite the obvious importance of this pathway in human physiology and development, and considerable attention and progress in the past 15 years, major questions about the signaling mechanism remain to be answered.

Most of our mechanistic understanding of PCP signaling comes from work in *Drosophila*, in which numerous tissues, including the wing, eye, and abdomen display manifestations of PCP ([Tree et al., 2002a](#); [Zallen, 2007](#); [Simons and Mlodzik, 2008](#)). Of these, the most thoroughly studied planar polarized tissue is the fly wing, in which each cell produces a trichome (or 'hair'), that in wild type emerges from the distal side of the cell and points distally ([Figure 1](#); [Wong and Adler, 1993](#)). During polarization of hair cells, cytoskeletal regulators are recruited to proximal and distal sides of the cell and control the localization of actin polymerization and bundling to ensure distal localization of hair emergence ([Wong and Adler, 1993](#); [Strutt and Warrington, 2008](#); [Yan et al., 2009](#); [Lu et al., 2010](#)). Mutants either fail to choose a side, thus producing a hair from the center of the cell, or choose an incorrect side, resulting in an incorrectly oriented hair. Cells of the

abdominal epithelium produce multiple posteriorly oriented hairs that emerge from the posterior side of the cell and point posteriorly.

Polarity in the eye results from the differentiation of the initially equipotent R3/R4 photoreceptor progenitors into an equatorial R3 and a polar R4 ([Figure 1](#)). Here, the key distinction is not between opposite sides of the same cell, but between adjacent sides of this pair of progenitor cells. A competition for Notch signaling activation between the R3/R4 pair becomes biased by the PCP signal at the intercellular junction so that the equatorial cell always expresses low Notch levels and becomes R3. PCP mutants lead either to incorrect R3/R4 fate decisions, or in some cases, indistinctly differentiated pairs of R3/R4 cells ([Zheng et al., 1995](#); [Cooper and Bray, 1999](#)).

On the notum, PCP controls the orientation of an asymmetric cell division in the sensory organ precursor (pI) cells. pI cells differentiate within the epithelium and divide asymmetrically to produce an anterior pIIb daughter and a posterior pIIa daughter cell. The PCP pathway distinguishes anterior and posterior sides of the pI cell through asymmetric interactions with its anterior and posterior neighbors. The pI cell therefore seems to become polarized much like the surrounding epithelial cells do, but it uses this polarity to position cell fate determinants and the mitotic spindle prior to an asymmetric division. PCP mutants cause this division to be incorrectly oriented.

Mechanosensory organs are composed of a multicellular bristle, and an associated bract ([Figure 1](#)). These organs are arranged in precise patterns, and have an intrinsic polarity that is evident at several levels. The bract, elaborated by a single cell, resembles a hair, and points distally. The shaft of the bristle points distally, similar to the bracts and hairs. In addition, the base of each shaft is surrounded by a socket cell, and the vector defined by each socket-bract pair points proximally. Each of these polarities can be disturbed by PCP mutants, and may vary independently ([Held et al., 1986](#)).

The molecular machinery that directs these morphogenetic events downstream of the core module is specific to the tissue. For example, during polarization of hair cells, cytoskeletal regulators are recruited to proximal and distal sides of the cell and control the localization of actin polymerization and

Figure 1 Manifestations of wild type and mutant PCP signaling. (a) Phalloidin stains showing the actin-based emerging hairs (prehairs) growing from the distal side of each cell and pointing distally in wild type, and growing from the center of the cell in a PCP mutant wing. Below, a cartoon of each cell, with green and red bars schematizing the subcellular localization of PCP proteins once cells are polarized. (b) Polarity in a wild-type and a mutant eye. Sections reveal the rhabdomeres of seven photoreceptor cells in each ommatidium, each forming a chiral structure with a particular orientation. In wild type, the two chiral forms are on opposite sides of an obvious equator, and point in opposite directions. In the mutant, chiralities are interspersed, and some ommatidia have symmetrical form. Many ommatidia are also misrotated. The schematic shows the PCP-dependent differentiation of the R3 and R4 cells, and subsequent rotation and morphogenesis of each ommatidium. (c) Bracts associated with mechanosensory bristles on the legs of a wild type and a PCP mutant fly. In wild type, the bract is always induced from the epithelial cell directly proximal to the socket and shaft (white arrow). In the mutant, one bract is correctly positioned (white arrow), while the other is incorrectly located on the distal side, and points proximally (blue arrow).

bundling to ensure distal localization of hair emergence (Wong and Adler, 1993; Strutt and Warrington, 2008; Yan *et al.*, 2009; Lu *et al.*, 2010). In contrast, tissue-specific control of bristle and bract polarization represents the interaction of the PCP modules with a more complex multicellular system (Peng *et al.*, 2012).

Clones of cells that are either mutant for a core PCP component or that overexpress a core component stereotypically perturb, or fail to perturb, the polarity of cells in nearby nonmutant tissue (Gubb and Garcia-Bellido, 1982; Vinson and Adler, 1987; Taylor *et al.*, 1998; Adler *et al.*, 2000). This is most obvious in the wing and eye, where arrays of polarizing cells are present (Figure 2). In the cases when polarity is perturbed, polarities are reversed to either abnormally point toward or away from the clone. This phenomenon is referred to as domineering nonautonomy, and together with the corresponding abilities of these clones to reorganize the localization of core PCP proteins in these cells (see below) has provided fertile ground for experiments aimed at understanding the mechanism of core PCP signaling.

In vertebrates, many aspects of PCP signaling identified in flies are conserved, but genetic analyses indicate that a more diverse array of morphologic events is controlled by the same components together with additional regulators not present in flies (Jones and Chen, 2007; Wang and Nathans, 2007; Zallen, 2007; Simons and Mlodzik, 2008). Here, we will focus on our emerging understanding of PCP signaling mechanisms derived from studies in flies.

A Modular Signaling System

Genetic and molecular analyses in several *Drosophila* tissues have identified components of the PCP signaling mechanism, and have suggested that they may be divided into three classes of functional modules: global directional modules, a core module, and a suite of tissue-specific effector modules that respond to the upstream modules to produce morphological asymmetry in individual tissues (Tree *et al.*, 2002a). The global directional modules link tissue-level directional information

Figure 2 Domineering nonautonomy near a *fz* and a *vang* mutant clone in the wing, visualizing the emerging prehairsts with phalloidin stain. Clones were genetically marked (not shown) and are surrounded by the yellow lines. In a wild-type wing, prehairsts point distally. Note that prehairsts are reoriented to point toward the *fz* clone and away from the *vang* clone (orange arrows). They therefore perturb polarity on opposite sides of the clone.

to local cell polarization. The core module amplifies molecular asymmetry within cells while linking the polarity of cells with their neighbors, producing a coordinated polarization across the tissue. The tissue-specific modules act as effectors for a diverse group of morphological readouts of the molecular polarity produced by the upstream modules.

The first recognized and best understood global module is the Fat/Dachsous/Four-jointed (Ft/Ds/Fj) module (Figure 3). This module serves to convert tissue-level expression gradients to subcellular gradients of Ft–Ds heterodimer localization (Mahoney *et al.*, 1991; Clark *et al.*, 1995, 2002; Adler *et al.*, 1998; Yang *et al.*, 2002; Ma *et al.*, 2003; Lawrence *et al.*, 2004). It consists of the atypical cadherins Ft and Ds, that form heterodimers which may orient in either of two directions at any apical cell–cell boundary, and the Golgi resident protein Four-jointed (Fj) (Villano and Katz, 1995; Zeidler *et al.*, 2000;

Yang *et al.*, 2002; Ma *et al.*, 2003). Fj acts as an ectokinase on both Ft and Ds (Ishikawa *et al.*, 2008), to make Ft a stronger ligand, and Ds a weaker ligand, for the other (Brittle *et al.*, 2010; Simon *et al.*, 2010). As Fj and Ds are expressed in gradients across tissues (Zeidler *et al.*, 1999; Casal *et al.*, 2002; Yang *et al.*, 2002; Ma *et al.*, 2003; Lawrence *et al.*, 2004), the result is a larger fraction of Ft–Ds heterodimers in one orientation relative to the other (Ma *et al.*, 2003). This molecular asymmetry is predicted to be subtle, but can be detected at early stages of development when the Ds and Fj gradients are steeper (Ambegaonkar *et al.*, 2012; Bosveld *et al.*, 2012; Brittle *et al.*, 2012). Many elements of this relatively elegant and simple model are likely to be correct, yet it is clear that it is far from a complete picture, and important puzzles remain. This mechanism will not be discussed at length here, as it was recently reviewed (Matis and Axelrod, 2013).

For some time, Wnts have been known to participate in PCP signaling in vertebrates (Vladar *et al.*, 2009; Goodrich and Strutt, 2011; Wallingford, 2012), and recently, a potential role for Wnts, likely as global signals, has been proposed in flies, where Wnt4 and Wg have been suggested to function as redundant signals that act near the wing margin (Wu and Mlodzik, 2008). The localized expression of these diffusible molecules at the wing margin suggests the possibility that they may signal by forming gradients, but little is yet known about their mechanism of action. Studies of the *Drosophila* abdomen have led to the suggestion of yet another type of global signaling information. The Ft/Ds/Fj mechanism clearly contributes to PCP in the abdomen, but may not explain all of global signaling function. To date, there is no firm evidence pointing to the identity of an additional global signal (Lawrence *et al.*, 2002).

The core module comprises the first recognized molecular components of PCP signaling. Several decades of study have led to the understanding that it acts both to amplify asymmetry, and to coordinate polarization between neighboring cells, producing a local alignment of polarity. Proteins in the core signaling module, including the seven-pass transmembrane protein Frizzled (Fz) (Vinson and Adler, 1987; Vinson *et al.*, 1989), the multi-domain protein Dishevelled (Dsh) (Klingensmith *et al.*, 1994; Thiesen *et al.*, 1994), the Ankyrin repeat protein Diego (Dgo) (Feiguin *et al.*, 2001), the four-pass transmembrane protein Van Gogh (Vang; a.k.a. Strabismus) (Taylor *et al.*, 1998; Wolff and Rubin, 1998), the Lim domain protein Prickle (Pk) (Gubb *et al.*, 1999), and the seven-transmembrane atypical cadherin Flamingo (Fmi; aka Starry night) (Chae *et al.*, 1999; Usui *et al.*, 1999; reviewed in Zallen, 2007), adopt asymmetric subcellular localizations that predict the morphological polarity pattern such as hairs in the fly wing (Usui *et al.*, 1999; Axelrod, 2001; Feiguin *et al.*, 2001; Strutt, 2001; Tree *et al.*, 2002b; Bastock *et al.*, 2003). These proteins form intercellular complexes that communicate at cell boundaries, recruiting one group to the distal side of cells, and the other to the proximal side, through the action of a poorly understood feedback mechanism, thus aligning the polarity of adjacent cells (Tree *et al.*, 2002b; Amonlirdviman *et al.*, 2005). Though not formally established, this mechanism has all the hallmarks of bistability. The unpolarized state is predicted to be metastable and an input bias, or fluctuations caused by

Figure 3 Schematics of the Ft/Ds/Fz global and the core modules. Organization of components at the junction between two cells is depicted. Gradients of Fz and Ds expression lead to a slight excess of Ft–Ds heterodimers at each interface. The core module is depicted as undergoing mutual inhibition, with the proximal components Vang and Pk disrupting the Fz–Dsh distal components. This particular competition was won by the upper complex, in the wild-type orientation.

noise, is expected to bias a coordinated polarization that will then amplify in magnitude. Indeed, this behavior has been captured by a variety of mathematical modeling frameworks for PCP signaling (Lawrence *et al.*, 2004; Amonlirdviman *et al.*, 2005; Le Garrec *et al.*, 2006; Le Garrec and Kerszberg, 2008; reviewed in Axelrod and Tomlin, 2011).

It is important to point out that the core module mechanism has no intrinsic directionality; allowed to polarize in the absence of a global directional signal, it is expected (and indeed seen in experiments and in simulations; reviewed in Axelrod and Tomlin, 2011) to achieve locally coordinated polarity that produces swirling patterns not respecting the global tissue axes. The global signals are therefore envisaged as providing subtle directional inputs that would both bias the initiation of polarization in a given direction and sustain the orientation of polarization during disrupting events such as cell divisions and morphogenetic rearrangements that require realignment of the polarization axis.

The segregation of proximal and distal core PCP proteins to opposite sides of the cell is a molecular marker of cell polarization, and correlates intimately with the various morphological polarization responses. For example, trichomes develop at the side of the cell where the distal proteins Fz and Dsh localize in wing cells, and Delta is activated and Notch repressed in the prospective R3 cell where Fz and Dsh localize (Figure 1).

Principles of Collective Polarization

On theoretical grounds, one can posit that generation of cell polarity requires two coordinated signaling events. First, accumulation of a cell polarity factor, P, must be self-enhancing, and second a long-range signal is required to inhibit accumulation of the same factor (Figure 4; Meinhardt, 2007). This has been modeled in single cells, and studied experimentally in systems such as budding yeast and migrating neutrophils, where, by definition, both signals are intracellular.

Figure 4 Cartoons of activities required for cell polarization in a single cell using only intracellular interactions (left) and using both intracellular and intercellular interactions (right).

Intracellular local self-enhancement can result from cooperative interactions between components of the polarity factor, for example. Long-range intracellular inhibition may result from a separate diffusing inhibitory molecule, or perhaps more simply, by limiting the amounts of one or more components of the polarity factor, thereby causing depletion and suppression of accumulation across the cell as a single locus stochastically becomes predominant and more rapidly accumulates the factor.

While the same principles apply in polarization of multicellular assemblies, the possibility for intercellular signaling provides additional routes to fulfill these two functions. Given a system with two polarity complexes that have the ability to recruit each other across intercellular boundaries like North and South poles of magnets, one can hypothesize that the intracellular long-range inhibition can be complemented, or even replaced, by an intercellular signal in which accumulation of North on one side of a given cell attracts components of South to the adjacent side of the neighboring cell. Since South and North repel each other, this will inhibit North from accumulating adjacent to its location in the first cell, thus providing a long-range inhibition, but in the neighbor rather than in the original cell. Furthermore, local self-enhancement can proceed by a related mechanism. North in the first cell attracts South in the neighbor, which repels North. By repelling North, accumulation of additional South in the first cell is

diminished. Physicists have thoroughly modeled these types of systems.

Feedback Control of Core Amplification

Experimental evidence suggests that the core PCP proteins function, at least in part, through intercellular interactions akin to those described above. The wild-type distributions of proximal and distal core proteins to opposite sides of the cell, and the rearrangements observed around mutant or over-expressing clones have long suggested just such a North–South relationship between proximal and distal proteins (see e.g., [Tree et al., 2002b](#); [Strutt and Warrington, 2008](#); [Wu and Mlodzik, 2008](#)), and this was eventually demonstrated formally ([Chen et al., 2008](#)). Here, North and South can be equated to Fz and Vang. Their interaction requires an additional factor, the atypical cadherin Fmi that forms homodimers that participate in the complex. Of the core PCP proteins, only Fmi is required, in both cells, to mediate this interaction.

The asymmetrically localized subcellular complexes, with Fz on the distal side and Vang on the proximal side of adjacent cells, communicate information bidirectionally between those cells ([Strutt and Strutt, 2007](#); [Chen et al., 2008](#)). This is perhaps most simply illustrated by the observation that cells on either side of adjacent *vang* and *fz* mutant clones both strongly polarize, indicating that cells with only the Fz complex and cells with only the Vang complex can strongly polarize a neighboring cell ([Strutt and Strutt, 2007](#)). Fmi homodimers are essential for this communication ([Usui et al., 1999](#); [Bastock et al., 2003](#); [Lawrence et al., 2004](#); [Strutt and Strutt, 2007](#); [Chen et al., 2008](#)). It has been shown that, rather than acting simply as a scaffold for complex assembly, information passes bidirectionally through the Fmi bridge that, although a homodimer, is functionally, and presumably structurally, asymmetric ([Chen et al., 2008](#)). This is evident from the observation that clones of cells overexpressing Fmi, but lacking both Fz and Vang retain the ability to repolarize neighboring cells. Competing models have alternately suggested that information only need flow through the Fmi homodimers ([Chen et al., 2008](#)), or that Fz and Vang directly interact to mediate signal transmission ([Wu and Mlodzik, 2008](#)).

According to this understanding, these components can provide the mutual recruitment needed, while the mutual inhibition needed for the North–South repulsion is thought to be provided by the cytosolic PCP factors Pk, Dsh, and Dgo. A more detailed discussion of how these interactions might occur follows below.

The recruitment of North and South across intercellular boundaries into complexes, in the form of Fz–Fmi:Fmi–Vang complexes, can occur in either orientation at any given intercellular boundary. Long-range intercellular inhibition requires that, in addition, North exclude South, or South exclude North, or both, within each cell. Only indirect evidence for this mechanism currently exists. This kind of model, on a conceptual level, was presciently proposed by [Adler et al. \(1997\)](#), but at the time, little molecular context was available ([Taylor et al., 1998](#)). A somewhat more explicit model was subsequently proposed based on the observation that Pk, which

accumulates with Vang (on the proximal side, in wild type), was able to block Fz-dependent recruitment of Dsh to the cell cortex in cell cultures. Coupled with the phenomenological observations that proximal and distal proteins always seem to segregate to opposite sides when polarization occurs, one could infer that mutual inhibition occurs ([Tree et al., 2002b](#); [Bastock et al., 2003](#); [Amonlirdviman et al., 2005](#)). However, the network of interactions has not been demonstrated, and it is difficult to parse out whether, at a wild-type intercellular junction, the exclusion of Fz/Dsh by Vang/Pk relies on exclusion within one cell or the loss of recruitment by the neighbor.

Asymmetric Fz–Fmi:Fmi–Vang complexes can form in the absence of the cytosolic factors, and can transmit polarity information under conditions in which differences are enforced between cells. When differences are not enforced between cells, Dsh, Pk, and Dgo functions are required for the feedback-mediated amplification of the asymmetry that develops at proximal–distal intercellular boundaries ([Lawrence et al., 2004](#); [Strutt and Strutt, 2007](#); [Chen et al., 2008](#)). In their absence, asymmetry is not amplified, and core PCP components remain more or less uniformly distributed around the cell.

As seen in wild type, core PCP proteins are not evenly distributed at intercellular junctions, but exist in uneven distributions, giving the appearance of being concentrated into aggregates, or puncta in some locations. This punctate appearance is greatly exaggerated with overexpression of Pk, one of the cytosolic proximal factors, and overall levels are increased ([Tree et al., 2002b](#); [Bastock et al., 2003](#)). Fluorescence recovery after photobleaching (FRAP) has been used to demonstrate that the puncta are indeed much more stable aggregates, at least for Fmi and Fz ([Strutt et al., 2011](#)). While membrane localization requires only Fz, Fmi, and Vang, the cytosolic factors are needed to induce stable aggregates. Unstable Fmi and Fz, or the fractions not in puncta, are subject to internalization and either recycling or degradation. Thus, the pools of core PCP components appear to exist in steady states of stable, aggregated complete complexes, less stable complexes consisting of Fz–Fmi:Fmi–Vang, and lower order, less stable subcomplexes. Pools of the unstable complexes are regulated by internalization. While additional detail about these processes is known, there is still no clear understanding of how the cytosolic factors produce amplification.

One hypothesis is that the cytosolic factors induce clustering, thereby providing the local cooperativity needed for polarization. The mechanism for clustering, or how it is enhanced by Pk, is not known. As previously proposed by [Strutt et al. \(2011\)](#), clustering may result from a scaffolding effect. These investigators dismissed the possibility of decreased endocytosis accounting for clustering.

The proximal protein Pk and the distal proteins Dgo and Dsh have been shown to engage in competitive binding interactions ([Tree et al., 2002b](#); [Jenny et al., 2003, 2005](#); [Das et al., 2004](#)). This suggests, first, that oppositely oriented complexes come into contact, and second, suggests the possibility that these interactions might result in disruption of one or the other complex. At present, this potential mechanism is speculative, but is appealing, and consistent with the early proposal by [Tree et al. \(2002b\)](#). Such a model would provide long-range intercellular inhibition that is needed for polarization.

System Architecture

Studies of polarity in the wing and eye first led to the proposal that the Ft/Ds/Fj global module provides directional information that orients the activity of the core module (Yang *et al.*, 2002; Ma *et al.*, 2003; Figure 5). This hierarchical, or series, architectural scheme derived from the observation that orientation of core PCP proteins and morphological polarity are coordinately disturbed in global mutant clones (Ma *et al.*, 2003), and from mosaic analyses in the fly eye showing that boundaries between cells expressing and not expressing *ft*, *ds*, or *fj* lost the ability to influence polarity in the absence of *fz* (Yang *et al.*, 2002). In contrast, others have argued for a parallel system architecture, with the proposal of a bypass pathway (green arrow) resting upon observations in the abdomen that clones overexpressing global components (Ds or Ds[ecto], a more active form of Ds) produce domineering non-autonomy and therefore influence polarity within tissue lacking either Fz or Fmi (Casal *et al.*, 2006; Lawrence *et al.*, 2007). The argument supporting this scheme is also not definitive (discussed at length in Axelrod, 2009). Furthermore, it was suggested that PCP in the larval epidermis depends on the global module, while the core module has no function in this context (Repiso *et al.*, 2010), although a more detailed study found that the core module does become important in this tissue as it grows (Donoughe and DiNardo, 2011). Thus, the extent to which the blue, green, and black pathways (Figure 5) contribute has been proposed to differ in different contexts. The extents to which they contribute, or whether they in fact contribute at all in some tissues, remain controversial. Furthermore, since the data leading to alternate architectures derive from different tissues, one must consider the possibility that the architecture differs in different tissues. For the purposes of this discussion, only the Ft/Ds/Fj global module will be considered, as there is little data connecting Wnt4/Wg to other systems, and the identity of other potential global systems is not known.

The Ft/Ds/Fj system has features that make it an attractive candidate for providing directional information in multiple tissues. The direction of ommatidial polarization in the *Drosophila* eye depends on Ds and Fj gradients, and these effects require an intact core module (Yang *et al.*, 2002). In the eye, flattening the gradients leads to near randomization of local polarity, and inversion of the gradients leads to reversal of local polarity (Simon, 2004). In the wing, the core PCP

proteins lose their orientation and polarize in swirling patterns in *ft* mutant clones (Ma *et al.*, 2003), and altering Ds expression patterns can reorient wing polarity (Matakatsu and Blair, 2004; Harumoto *et al.*, 2010). In the abdomen, opposing gradients of Ds and Fj are also observed, and these have opposite directions in anterior and posterior compartments of each segment (Casal *et al.*, 2002), and mutants demonstrate that they are needed for normal polarization. These observations are all consistent with a global directional function for the Ft/Ds/Fj module, acting upstream of, and in series with, the core module.

However, several observations are less simply reconciled with this model. When Ds and Fj, normally expressed in gradients along the proximal–distal (P/D) wing axis, are instead expressed uniformly, polarity is disrupted only in the proximal part of the wing (Matakatsu and Blair, 2004; Simon, 2004). In the abdomen, ectopic Ds expression can reorient tissue mutant for the core factors *fz* and *fmi* (Casal *et al.*, 2006). This would not be expected if the role of the Ft/Ds/Fj module is to provide directional information to the core module. Hence, this model is controversial, and others have proposed instead that the Ft/Ds/Fj and core modules function in parallel, acting independently on downstream effectors, and leaving open the question of what cues might orient core module function (Casal *et al.*, 2006).

In the face of the uncertainty about the relationship between the Ft/Ds/Fj module and the core module, the outlines of a unifying hypothesis that connects them in series have begun to emerge.

The first important observation is that microtubules appear to play a central role in the global alignment of PCP in the developing *Drosophila* wing. An unusual apical microtubule cytoskeleton (Eaton *et al.*, 1996; Shimada *et al.*, 2006; Harumoto *et al.*, 2010) can be seen in cells of the fly wing during polarization. During efforts to study the dynamics of Fz using a Fz::GFP transgene and live imaging, Shimada *et al.* (2006) noticed that what appeared to be vesicles can be seen departing the apical membrane, traversing the cell, and fusing to another side. Correlation to immuno-electron micrographs lends support to the notion that these were indeed Fz-containing vesicles that are associated with microtubules. A quantitative analysis showed that these vesicles move with an overall distal bias. Remarkably, using EB1::GFP, a marker of microtubule plus-ends, it was seen that the microtubules have a corresponding bias of distal plus-ends.

Vesicle movement was most active during the most dynamic period of polarization, and vesicle production depended on other core PCP proteins (Shimada *et al.*, 2006). From these data, biased trafficking could be inferred to be important in PCP acquisition, but whether this process was intrinsic to the core mechanism, or perhaps reflected a directional input, could not be discerned. However, a telltale clue was that the microtubule structure itself appeared not to depend on the core module. In a subsequent report, Harumoto *et al.* (2010) showed that the polarity of the microtubules depends on Ds, a component of the Ft/Ds/Fj module. This was consistent with evidence that Ft influences apical microtubule organization in another context (Marcinkevicius and Zallen, 2013). Plus-end bias was perturbed in *ds* mutants, and misexpression of Ds could reorganize microtubule polarity. These experiments were

Figure 5 Possible architectures of the Ft/Ds/Fj global and the core modules in relation to the effector modules.

complicated by the lethality associated with *ft* mutants, precluding a more thorough analysis, but suggested the possibility that the Ft/Ds/Fj global module organizes microtubules that in turn directionally bias core module polarization.

It is therefore tempting to hypothesize that polarized apical microtubules that transport Fz might comprise the Ft/Ds/Fj global directional signal that orients core PCP protein segregation. This hypothesis makes a number of predictions that remain to be tested. First, the oriented microtubules should appear and be polarized prior to the onset of core polarization. Second, there should be a spatiotemporal relationship between the orientation of apical microtubules and core polarization. This is of greatest interest in the wing, where substantial morphogenetic changes occur between third instar, when polarization begins, to the conclusion of polarization in the pupal stage, when hairs begin to grow. Finally, a more detailed analysis of the contributions of Ft/Ds/Fj to microtubule organization is needed.

The above hypothesis is based on data from the wing, yet the phenotypes and expression patterns, in particular the graded expression, of Ds and Fj suggest that they might have similar roles in other compartments. However, at first glance, there is an important inconsistency. If one imagines that the gradients of Ds and Fj organize microtubules, and thereby vesicle transport, in such a way that Fz accumulates toward low Ds and high Fj, this is observed in the wing and posterior abdomen, but the relative orientations are opposite in anterior abdomen and eye (Zeidler *et al.*, 2000; Casal *et al.*, 2002; Ma *et al.*, 2003; Matakatsu and Blair, 2004; Rogulja *et al.*, 2008; Axelrod, 2009).

Because the relative orientations of the Fj and Ds gradients with respect to the direction of core protein polarization is not conserved in wing, eye, and abdomen, universality of the model described above requires that one explain how oppositely oriented inputs can be rectified to produce similarly polarized outcomes. A clue to this rectification puzzle comes from the observation that tissues in which Fz and Dsh accumulate toward high Fj (wing and posterior abdomen (P-abd)) rely on the Pk but not the Sple isoform of Pk-Sple, while tissues in which Fz and Dsh accumulate away from high Fj (eye and anterior abdomen (A-abd)) rely on the Sple isoform; in wing and P-abd, polarity is disturbed in mutants of the *pk^{pk}* but not *pk^{sple}* isoform of the *pk* gene, whereas eye and A-abd are sensitive to *pk^{sple}* but not *pk^{pk}* (Gubb *et al.*, 1999; Lawrence *et al.*, 2004). One can therefore infer that Pk is the predominantly expressed or active isoform in wing and P-abd, while Sple is predominant in A-abd and eye.

Furthermore, clues suggest that the direction of gradient interpretation might depend on the predominant isoform present in each tissue. Manipulating *pk* and *sple* expression in wing and abdomen can alter the direction of polarization with respect to the Ft/Ds/Fj gradients. More specifically, overexpression of the non-predominant isoform in wing or either abdominal compartment can at least partially reverse polarity (Lawrence *et al.*, 2004; Lin and Gubb, 2009; Doyle *et al.*, 2008; Hogan *et al.*, 2011). This suggests that Pk causes hairs to point toward high Fj, while Sple caused them to point toward low Fj. Indeed, a subsequent analysis has shown that Pk and Sple cause the opposite orientation of microtubules with respect to the Fj and Ds gradients, and therefore the trafficking of

Fz vesicles that could orient the core module is opposite (Olofsson *et al.*, 2014). The relative expression of these isoforms therefore can rectify the upstream signal to orient core module polarization.

Outlook

The past two decades have witnessed a leap in understanding the signals that control PCP, with the advances powered primarily by standard approaches employed in genetic models. Continued progress is likely to require the deployment of other approaches less commonly combined with traditional genetics, including biophysical, proteomic, cell biological, and biochemical studies. Meanwhile, the complex relationship between mutation and phenotype will demand the continued use of mathematical modeling to relate molecular interventions to pattern outcomes for a given network signaling model.

Signals to Migrate

Overview

What signals trigger a cell to migrate, and instruct it in what direction to move? Cells translocate in response to cues from the extracellular environment. In general terms, ligand binding and activation of growth factor receptors on the cell surface triggers elaborate and potent intracellular signaling cascades that can induce changes in cytoskeletal and membrane dynamics, leading to cell migration. The precise signals that activate cell movement depend on the context and on the target cell. Yet the general concepts are highly conserved: first, extracellular signals are relayed through receptors on the cell surface to stimulate intracellular signaling pathways. These signals are transmitted into biochemical, cytoskeletal, and mechanical changes that ultimately induce cell migration (Figure 1).

Directed Cell Migration

Whenever cell migration is required, it is not sufficient for the cell to migrate randomly, but rather, the cell must migrate in a specific direction. In order to achieve directional migration, the cell must establish polarity (i.e., a front, or leading edge and a rear, or trailing edge). This results from the exposure to a gradient. These gradients may be quite shallow, but even these subtle differences across the body of a cell can lead to localized changes at the site of the gradient signaling resulting in polarization, and the establishment of directional migration. These polarized signals include the generation of specific

phospholipids and the activation of calcium signaling pathways that result in the generation of localized, asymmetric forces that can cause the cell to migrate in the indicated direction. In addition, in response to a mitogenic signal, cells reorient the Golgi apparatus and microtubule cytoskeleton in the direction of migration. These concerted processes of polarization regulate the persistent, directional migration of a cell (Figure 2; Rorth, 2011; Bear and Haugh, 2014; Majumdar *et al.*, 2014).

Chemotaxis

Chemotaxis is the directed migration of a cell in response to a chemical stimulus, such as a growth factor. The specific ligands and receptors used in chemotaxis vary among cell types, as do the specific mechanisms used to relay chemotactic signals. For example, migrating leukocytes can rapidly sense and respond to a chemotactic gradient to respond to tissue damage or infection. The migration used by leukocytes is generally mediated by chemokines (such as CXCL12, CXCL13, and IL8) that bind to their cognate G-protein coupled receptors (GPCRs). Signaling through GPCRs can be rapidly turned off through desensitization. This allows an adaptation to the signal, and is compatible with the rapid and early migration of neutrophils and lymphocytes in response to an insult (Jin, 2013).

Chemotaxis mediated by receptor tyrosine kinases (RTKs), which tends to be slower than that of GPCR-induced chemotaxis, is generally utilized by fibroblasts and epithelial cells. Like signaling through GPCRs, RTK signaling can induce localized changes in activation of signaling molecules that result in changes in cell adhesion and cytoskeletal remodeling. A classic example of chemotactic migration in fibroblasts

Figure 1 Cytoskeletal changes drive morphological changes and cell migration. Activation of signal transduction pathways can induce protein modifications that result in actin cytoskeletal remodeling. Here, a cultured Clone 9 rat hepatocyte is not highly migratory under steady-state conditions (left). However, expression of a mutated form of the protein cortactin, which binds and regulates actin dynamics, induces a dramatic shape change and promotes migratory behavior (right). Reproduced from Kruchten, A.E., Krueger, E.W., Wang, Y., McNiven, M.A., 2008. Distinct phospho-forms of cortactin differentially regulate actin polymerization and focal adhesions. *American Journal Physiology Cell Physiology* 295 (5), C1113–C1122, with permission from The American Physiological Society. Note the formation of multiple dynamic lamellipodia structures (arrows, described below). This mutated version of cortactin mimics phosphorylation by the kinase Src, which is a potent signaling pathway that links extracellular stimuli to cytoskeletal changes (YE=Y384E, Y429E, Y445E).

Figure 2 Directed cell migration. (a) In response to a gradient of a migratory stimulus, ligand (orange) associates with cellular receptors (brown) to induce asymmetric signal transduction. This leads to redistribution of the Golgi (gray stacks) and MTOC and microtubule cytoskeleton (green), and polarized actin cytoskeletal remodeling to drive migration in the direction of the gradient (open arrow). (b) Clone 9 rat hepatocytes exhibiting directional migration in a wound healing assay. The cells were grown to a confluent monolayer, the monolayer was then scratched, and the cells began to migrate into the gap. Migrating cells re-orient their Golgi (GM130 stain, red) and microtubules (acetylated microtubules, green) in the direction of migration (open arrow), in contrast to the cells further back, which are still nonpolarized.

occurs through the platelet-derived growth factor (PDGF). PDGF, signaling through its receptor, regulates phosphoinositide signaling through PI3K, calcium signaling through PLC γ , cell adhesion through focal adhesion kinase (FAK), and Ras and MAP kinase signal transduction (Ronnstrand and Heldin, 2001).

Haptotaxis

Whereas in chemotaxis cells migrate in response to secreted ligands, in the process of haptotaxis, cells encounter immobilized ligands, such as extracellular matrix (ECM) proteins, and these ligands promote directional migration. Cells extend protrusions that encounter such ECM proteins, including collagen, which engage proteins such as integrins on the cell membrane. Integrin activation links the ligand to the actin cytoskeleton of the migrating cell, thus regulating cellular adhesions, formation of more protrusions, and persistent migration. The molecular mechanisms of haptotaxis are similar to that of chemotaxis, but also have significant differences in regards to the machinery regulating the actin cytoskeleton (Wu *et al.*, 2012).

In a related process, cells may migrate in response to ligands that are bound in the extracellular matrix. For example, dendritic cells migrate in the direction of a gradient of the chemokine CCL21. This ligand is immobilized by binding to heparin sulfate in the extracellular matrix, and thus the dendritic cell migrates through the ECM (Weber *et al.*, 2013). While these two processes of migration following stationary cues are very similar, it is unknown if the mechanisms behind their migration are the same.

Mechanotaxis

In addition to being driven by soluble chemical signals, directional migration can also be established in response to structural or mechanical cues. These mechanical cues are often provided by the extracellular matrix, which can vary in composition and in stiffness. For example, fibroblasts tend to

migrate toward matrix of increasing stiffness, in a process called durotaxis. Migrating cells can sense mechanical properties of the matrix through integrins and focal adhesions, structures that can also exert force on the matrix (described below) (Oakes and Gardel, 2014; Plotnikov and Waterman, 2013).

Signals to Migrate During Development

Early embryonic development is a period of intensive cell division and migration, and this migration is absolutely critical for patterning and organ development. Developmental migration is precisely regulated both temporally and spatially to form the distinct germ layers of the embryo and establish specific tissue organization. In early development, cells of the neural crest undergo dramatic migration and give rise to multiple different cell types. Cells migrate either individually or collectively, with their migration regulated by secreted factors, interactions with other cells, and interactions with the extracellular environment.

Migration in neural development

As one example, during the formation of the nervous system, developing neurons can migrate over significant distances, following an extremely precise route, including turning at specific landmarks, to form the appropriate synapses (Cooper, 2013). This process is exemplified by the dynamic and highly specialized leading edge of the developing axon, called the growth cone (Vitriol and Zheng, 2012). The migration of the growth cone is guided by positive, chemoattractive cues, and also balanced by negative, chemorepulsive cues, including the Semaphorin, Slit, and ephrin families of proteins. Some protein factors, including the netrins, can be either attractive or repulsive, depending on the context. These chemical cues signal through their cognate receptors expressed on the migrating neuron to active intracellular pathways that subsequently

regulate calcium signaling and cytoskeletal changes leading to migration.

Migration in vascular development

As a second example of cell migration in development, endothelial cells undergo significant migration during both the processes of vasculogenesis (the *de novo* vascularization of an embryo) and angiogenesis, the creation of new blood vessels from existing vessels. Endothelial cells are stimulated to migrate by ligands including vascular endothelial growth factor (VEGF), the most prominent regulator of angiogenesis, and basic fibroblast growth factor (bFGF), as well as by interactions with the extracellular environment including collagen and integrins, transmembrane proteins expressed by the migrating cell (Lamallice *et al.*, 2007).

Signals to Migrate in Physiological/Pathological Processes

In addition to migration's critical developmental functions, cell migration is also essential to maintain homeostasis in the adult. Multiple cellular processes require migration, regulated by distinct chemical and mechanical signals signaling through cell-specific receptors. Even with this diverse array of upstream activators of signaling, the general mechanisms of regulation are conserved: extracellular cues are translated into intracellular signaling pathways that ultimately affect the cytoskeletal architecture, membrane dynamics, and adhesive properties that contribute to cell migration.

Wound healing

In response to wounding, there is a dramatic mobilization and recruitment of multiple cell types that will serve to repair the wound (Werner and Grose, 2003). Fibroblasts migrate into the wound in response to platelet-derived growth factor (PDGF, produced by platelets that have infiltrated the wound to promote clotting), where the fibroblasts then proliferate, and eventually lay down the collagen matrix that will be the structural support for wound healing and closure. Leukocytes including neutrophils and macrophages migrate into the wound in response to hydrogen peroxide and chemokines including RANTES/CCL5, MCP1 (CCL2), and macrophage inflammatory protein 1a (MIP1a/CCL3), respectively (Nietzhammer *et al.*, 2009; Mahdavian Delavary *et al.*, 2011). These immune cells participate in inflammation following wounding, and remove any pathogens and damaged tissue. The need to repair and regenerate blood vessels requires the pro-angiogenic migration of endothelial cells to the wound site in response to VEGF and FGF family ligands. Finally, migration of keratinocytes is required to form the new protective barrier that will ultimately close the wound (Raja *et al.*, 2007). Keratinocyte migration is stimulated by keratinocyte growth factor (KGF, in the FGF family), insulin-related growth factors, and chemicals such as nitric oxide. Keratinocytes stop migrating in response to contact inhibition, when in contact with other cells.

The immune response

Leukocytes depend on motility for a competent, systemic immune response. These cells must migrate through the

vasculature and migrate across cellular barriers in order to reach damaged or infected tissues. While in circulation, leukocytes engage in a rolling-type migration, whereby they weakly adhere to the endothelial wall through interactions between transient interactions between selectins on the endothelium and their ligands on the leukocytes (Zarbock *et al.*, 2011). To stimulate migration out of the circulation and into the target tissue, signals from the target tissue come in the form of chemokines, such as IL-1 β , TNF α , and other factors. These chemokines trigger adhesive changes in both the endothelium and leukocytes to arrest the migration of the leukocyte in the circulation. The immune cells then undergo the invasive and dynamic process of transendothelial migration called diapedesis (Heemskerk *et al.*, 2014; Muller, 2011). To cross the endothelial barrier out of the circulation, the leukocytes undergo significant deformation to pass through the gaps between cells. While few cell types are able to undergo this aggressive transmigration, the mechanisms of cytoskeletal regulation allowing the cellular changes are similar to other mechanisms of cell migration, including polarization, actin cytoskeletal remodeling, and membrane dynamics.

Cytoskeletal Changes Underlying Migration

Overview

Even with the diverse array of signals that can stimulate cell migration in different contexts, the general mechanisms for translating these motogenic signals into mechanical changes that promote cellular locomotion are conserved among cell types and species. Cell migration is primarily driven by cytoskeletal and membrane changes related to the dynamic remodeling of the actin cytoskeleton (Graziano and Weiner, 2014; Ridley, 2011). This results in the formation of transient structures that can propel a cell forward by one of several major mechanisms.

Regulation of Migration by Rho Family GTPases

The formation of dynamic, actin-based migratory structures is regulated by the activation of a family of small GTP-binding proteins, the Rho family of GTPases. These proteins, including Rac1,2,3, Cdc42, and Rho, are small, 21-kDa proteins that function as molecular switches (Figure 3). In their active form, they bind to GTP, and this GTP-bound form is able to bind to effector proteins. These effectors only bind the GTP-bound form of the protein. Once the GTP is hydrolyzed to GDP, the effectors are no longer able to bind the complex. Thus, the GTP-state of the Rho GTPases is a potent way to regulate cytoskeletal remodeling and migration.

Activation of Rho GTPases

Rho family GTPases are activated downstream of the receptor/ligand interactions described above. Rho GTPases do not have intrinsically high GTP hydrolysis activity, and thus, by themselves, would not change their activation state very readily. Rather, their GTP binding, and hence activation, is regulated by a host of associated proteins (Figure 3). Guanine nucleotide exchange factors (GEFs) are a family of proteins that

Figure 3 Rho GTPase activation cycle. (a) The Rho GTPases Rac, Cdc42, and Rho are molecular switches that are active when bound to GTP. This allows binding to effector molecules leading to polymerization or branching of the actin cytoskeleton. Rho family GTPase activation is catalyzed by GEFs, which promote GTP binding. Inactivation of Rho GTPases is due to GTP hydrolysis, regulated by GAPs. (b) Activation or overexpression of GEFs can induce GTPase activation and cell migration. A PANC1 pancreatic cancer cell overexpressing the GEF Vav1 (yellow cell) has dramatically upregulated Rac activation, lamellipodia formation, and increased migratory capacity compared to the neighboring, nonexpressing cells (green).

facilitate the release of GDP from the small G-protein, which allows the binding of GTP, which is at much higher cytoplasmic concentrations, thereby promoting activation of the GTPase. Therefore, GEFs are potent activators of Rho family GTPases. Guanine nucleotide associated proteins, or GAPs, promote the hydrolysis of GTP, leaving the protein in the inactive, GDP-bound state. Finally, GDI proteins (Rho GDP-dissociation inhibitors) can also regulate GDP/GTP exchange, as well as the targeting or localization of specific Rho family GTPases.

As activators of GTPases, GEFs have received considerable attention for a role in driving cell migration (Goicoechea *et al.*, 2014). Over 40 different GEF proteins have been identified for the Rho family. Some have cell-type specific expression patterns, but it is undefined how signals from so many different GEFs are regulated, and which are functionally redundant. GEFs contain domains that perform the exchange, such as a Dbl homology domain (DH) in the Dbl family of GEFs, or a DHR2 domain in the DOCK family. These domains coordinate the binding of GDP and a magnesium ion on the GTPase, causing a conformational change to release the GDP. The exchange activity of GEFs can be regulated acutely to lead to responsive changes in the activation of Rho GTPases. GEFs can be activated by posttranslational modifications such as phosphorylation, by changing the localization or membrane association of the GEF within the cell via phosphoinositide binding, or by regulating the protein stability. Finally, many GEFs have been found to be overexpressed in cancer, in which an upregulation of cell migration contributes to metastasis, the spread of cancer cells throughout the body.

Signaling downstream of Rho family GTPases

Active, GTP-bound Rho family GTPases bind directly to effector proteins that relay the activating signal to downstream proteins that remodel the actin cytoskeleton. For example, active Rac/Cdc42 bind to the p21 activated kinase, or PAK. This kinase has multiple substrates that regulate cell survival and migration, including a subunit of the Arp2/3 complex (Rotty *et al.*, 2013). This protein complex induces actin

nucleation and branching, thereby contributing to the formation of cellular protrusions including lamellipodia. Rho GTPases also lead to the activation of WASP/WAVE proteins, which also regulate actin dynamics via Arp2/3 (Takenawa and Suetsugu, 2007). Actin remodeling contributing to cell migration is a coordinated process involving the severing of existing filaments to generate new barbed ends, the action of actin capping proteins to restrict polymerization, the branching mediated by Arp2/3, and the bundling and cross-linking of actin filaments.

Interestingly, there is considerable cross-talk between Rho and Rac/Cdc42. Generally speaking, Rho signaling opposes Rac/Cdc42, and vice versa. Each can promote a distinct type of cell migration, and the effectors of one GTPase may directly inhibit the activation of the other through downstream effector molecules.

Different Types of Cellular Migration

Depending on the cell type and on the environment, cells can utilize multiple types of migration. These each utilize different types of migratory structures, and are activated by different signaling pathways. Importantly, cells can rapidly switch from one style of migration to another depending on the extracellular environment, including matrix density and tension, the type of substrate, or the structural barrier (Figure 4; Petrie and Yamada, 2012).

Lamellipodial migration

Mesenchymal-type cells, such as fibroblasts, migrate forward through the formation of cellular protrusions called lamellipodia. In cell culture on a flat substrate, these structures are broad and flat (the lamella) with thin, dynamic leading edges (the lamellipodia) that are the sites of active actin polymerization and branching. Cells may also extend filopodia, thin, narrow protrusions that are thought to be involved in sensing the environment. Mesenchymal migration requires the destruction or remodeling of the extracellular matrix in order to allow the cell to pass (Bisi *et al.*, 2013; Ridley, 2011).

Type of migration	Lamellipodial	Amoeboid	Lobopodial
GTPase regulation	Polarized Rac/Cdc42 activation at leading edge	RhoA-mediated Myosin II activity at blebs	Nonpolarized RhoA-mediated Myosin II activity
Actin structures	Lamellipodia and Filopodia at leading edge; Rho-mediated stress fibers	Actomyosin contraction. No stress fibers	Actomyosin contraction Rho-mediated stress fibers.
Adhesion to ECM?	High – focal contacts	Low	High – focal contacts
Requires matrix degradation?	Yes	No	No

Figure 4 Modes of cell migration in 3D. Fibroblasts can rapidly switch among cell migration methods depending on the extracellular matrix environment. Modeled after [Sixt \(2012\)](#).

Lamellipodial migration is regulated by the small G-protein Rac1. GTP-bound Rac signals downstream to effectors including PAK, N-WASP, and WAVE proteins. These proteins promote branching of the actin cytoskeleton that is driven by the Arp2/3 protein complex, which introduces a new core of nucleation along an existing actin filament. The new actin filament branches at a 70 degree angle, and this polymerization and branching drives the formation of the lamellipodia.

Filopodial formation is regulated by the small G-protein Cdc42. This signals to activate WASP/N-WASP, which then activates actin polymerization and extensions of parallel actin bundles into the protrusive filopodia, with polymerization occurring at the filopodial tip. The filaments are cross-linked by actin binding proteins such as fascin.

Amoeboid migration

Cells are also able to migrate in a way that causes significant deformation of the cell in order to squeeze through gaps in the matrix. This is called amoeboid migration, or blebbing migration, as it resembles the streaming movement of an amoeba through the formation of membrane blebs. Amoeboid migration does not require proteolytic cleavage of the matrix. Rather, the cell finds a path through the ECM using blebbing protrusions. Thus, amoeboid migration can be activated rapidly and utilized in the absence of proteolytic matrix degradation ([Wolf et al., 2003](#)).

In contrast to mesenchymal, lamellipodial-based migration, which is regulated by Rac/Cdc42, amoeboid migration is regulated by signaling through RhoA, which is associated with force generation ([Lessey et al., 2012](#)). Whereas the extension of lamellipodia is driven by actin polymerization and branching, amoeboid migration is regulated instead by actin–myosin-based contraction. Actin–myosin contraction is best known for its role in muscle contraction, where myosin heads make and break contacts with actin to ‘walk’ along the actin and induce

contraction. Similarly, non-muscle myosins can generate contraction forces to change cell tension and shape, thereby inducing a mechanical component. Rho signals to the kinase ROCK, which promotes the phosphorylation and activation of the myosin light chain kinase (MLCK). MLCK then promotes Myosin II activity to regulate actin–myosin contraction. This results in the formation of constriction rings to form blebs, followed by the streaming of cytoplasm through the contracted neck.

Lobopodial migration

More recently, a distinct type of cell migration was described through the formation of structures named lobopodia. These structures, previously described in amoebas, were found in migrating fibroblasts in 3D cultures. Under matrix conditions of linear elasticity, fibroblasts can switch to lobopodial-style migration. This structure requires high Rho activity and mechanical stress, like amoeboid migration, but also require adhesion with the extracellular matrix, like mesenchymal movement ([Petrie et al., 2012](#)).

Cell Migration Is Regulated Through Interactions with the Environment

Overview

While many studies of cell migration have been done using two-dimensional cell culture on a glass or homogenous substrate, cell migration *in vivo* in a three-dimensional environment occurs in the presence of many more physical barriers. Cells *in vivo* exist in the context of a complex extracellular matrix, and in order to migrate, must break and reform contacts with the ECM. Further, cells often need to migrate through the ECM, which may require degradation or remodeling of the extracellular matrix to allow their passage.

Figure 5 Focal adhesions. (a) The focal adhesion mediates contact between the cell and the extracellular matrix through integrin heterodimers (α , β). Over 150 proteins have been identified in the focal complex: examples are shown, including some proteins that couple integrin signaling to the actin cytoskeleton. Rat fibroblasts (b) or human fibroblasts (c) stained for paxillin (green) and actin (red) show prominent paxillin-positive focal adhesions that are anchoring points for actin stress fibers.

Finally, in addition to contacts with the extracellular matrix, cell migration is also regulated by interactions with other cells, which may work in concert to migrate collectively, rather than as single cells.

Focal Adhesions

Cells form specialized structures called focal adhesions that link the extracellular matrix to the cytoskeleton. Focal adhesions consist of many structural and mechanosensing proteins clustered around integrins, transmembrane proteins that bind ECM proteins on the outside of the cell, such as fibronectins (Figure 5; Huttenlocher and Horwitz, 2011; Geiger *et al.*, 2009). Inside the cell, the focal adhesion is comprised of multiple proteins including paxillin, vinculin, and talin, which are linked to actin fibers. Thus, focal adhesions are able to both sense and respond to mechanical stress from inside and outside the cell (Ciobanasi *et al.*, 2013; Kuo, 2013; Schwarz and Gardel, 2012). Focal adhesions are also regulated by the microtubule cytoskeleton, which are proposed to be involved in targeted trafficking to and from the focal adhesion (Stebbens and Wittmann, 2012). Focal adhesions form as nascent focal complexes, which then mature to larger, more stable focal adhesions. These structures form in both two-dimensional and three-dimensional contexts, and stabilize the cell's position and modulate migration (Figure 5).

To begin cell migration, cells must break these focal adhesions (Nagano *et al.*, 2012; Wehrle-Haller, 2012). This occurs in response to signal transduction pathways activated by receptor tyrosine kinases, including phosphorylation by the kinase Src and focal adhesion kinase (FAK). These potent kinases phosphorylate components of the focal adhesion and lead to its disassembly. In addition, the integrin complex is internalized by endocytosis, thereby removing the integrin from the cell surface and dissociating the interaction with the ECM.

Matrix Remodeling During Migration

Migrating cells often need to cross a barrier to migrate to their appropriate destination. Thus, cell migration may be coupled with degradation or remodeling of the extracellular matrix. In particular, mesenchymal style migration is associated with

matrix destruction. Some cells, such as macrophages and osteoclasts, form specialized structures called podosomes that are based on the actin cytoskeleton and serve as sites of localized protease activity to degrade extracellular substrates. In cancer cells, similar structures, called invadopodia, are regulated slightly differently and have different dynamics, but accomplish a similar function, which is the degradation of the matrix to allow migration across barriers (Figure 6). In addition, focal adhesions have also been described as a matrix-degrading structure. The molecular components of focal adhesions and invadopodia are highly similar, and degradation of the ECM is likely coupled with migratory structures including lamellipodial protrusions and focal adhesions (McNiven, 2013; Murphy and Courtneidge, 2011; Hoshino *et al.*, 2013).

Matrix degradation is accomplished by secreted or membrane-tethered proteases, proteins that can specifically degrade extracellular matrix proteins such as collagens or fibronectins. These proteases include the matrix metalloproteinases (MMPs) and the ADAM proteases. These proteases are highly regulated by both positive regulators, which may cleave and activate the proteases, and by negative regulators, including the TIMPs for matrix metalloproteinases. Matrix degradation allows invasive cell migration, but must be tightly regulated to maintain tissue integrity and prevent aberrant migration. Matrix-degrading proteases such as the MMPs are frequently overexpressed in tumors, which contribute to metastatic invasion (Lu *et al.*, 2011; Kessenbrock *et al.*, 2010).

In addition to matrix degradation, cells such as fibroblasts produce new matrix. This matrix remodeling is important in replacing matrix that was lost during invasion or injury, and can serve as tracks for migration. For example, invasive tumor cells can migrate along collagen fibers, which are produced by cancer-associated fibroblasts that are activated by their association with tumor cells (Egeblad *et al.*, 2010).

Collective Cell Migration

Many of the pathways described here regulate the migration of individual cells. Cells are also able to migrate collectively, or in groups, while still maintaining contact with other cell (Figure 7; Rorth, 2012; Friedl and Gilmour, 2009; Etienne-Manneville, 2014). This collective cell migration is common during development, when entire sheets of cells migrate to

Figure 6 Matrix remodeling during migration. Degradation of the extracellular matrix is often required for cell migration *in vivo*. (a) Matrix degradation can be measured using cultured cells by plating cells on a fluorescent gelatin substrate, and measuring the loss of fluorescence (blackened areas). Here, a BxPC3 pancreatic cancer cell plated on a fluorescent gelatin matrix leaves a trail of degraded matrix in its wake as it migrates across the substrate. (b) Matrix degradation can be accomplished by actin-based protrusions called invadopodia (positive for actin, red, and arrows), that are sites for protease targeting to degrade the fluorescent gelatin matrix. (c) HPAF-II pancreatic cancer cells degrade matrix and migrate across a transwell filter, in an *in vitro* approximation of invasion that couples matrix degradation and migration. The image is a slice from a 3D rendering of a z-series using confocal microscopy of HPAF-II cells stained for actin (red) and DAPI (blue) on the underside of a filter in a transwell assay. (d) 3D reconstruction from confocal microscopy showing HPAF-II cells on the top and bottom of a transwell filter. In (c) and (d), note that the cells have degraded a barrier and migrated through the small pores in the filter (black circles).

Figure 7 Collective cell migration. (a) During collective migration, many cells influence one another as they all migrate in the same direction, such as a sheet or stream of cells that remain attached through cell-cell junctions. The population is comprised of one or more 'leader' cells, which utilize different signaling pathways than the follower cells (shown by red line). (b) PANC1 pancreatic cancer cells plated in a 3D matrix of Collagen I/Matrigel exhibit collective migration away from the spheroid of cells. Multiple cells follow a leader cell that degrades the ECM with α -actinin-rich protrusions. Green: α -actinin, Red: Actin, Blue: DAPI.

support the formation of tissues. The migrating cells may be tightly held together by adherens junctions, or may be more loosely associated, yet still migrating as a population. During collective migration, the cluster of migrating cells may display some of the same polarization and molecular signaling events as during single cell migration, but with different cells in the group exhibiting distinct properties. For example, one or more cells may serve as the leader cell, extending protrusions and responding to stimuli from the extracellular environment. Leader cells have different gene expression, distinct cell shape, and activation of differential signaling molecules compared to the follower cells. This process of collective cell migration is highly conserved across species, and is also utilized by tumor cells during metastatic migration.

Glossary

Angiogenesis Formation of new blood vessels by sprouting of existing vessels.

Blastema Group of cells capable of proliferation and regeneration into organs or body parts.

Carcinoma Cancer originating from epithelial cells.

Dermis Layer of the skin consisting mainly of connective tissue with embedded fibroblasts, some immune cells, and blood and lymphatic vessels. It is located below the epidermis and above the subcutaneous adipose tissue.

Epidermis The most upper layer of the skin, which includes keratinocytes at different stages of differentiation, some immune cells, as well as Merkel cells. The epidermis forms an inside-out and outside-in barrier to the environment.

Fibroplasia Fibroblast accumulation and their deposition of extracellular matrix.

Granulation tissue A cell-rich and highly vascularized tissue that replaces the fibrin clot in a skin wound.

Hemidesmosome Attachment site between the basal surface of certain epithelial cells and the underlying

basement membrane. Hemidesmosomes are anchored to the keratin cytoskeleton of epithelial cells.

Keloid Excessive scar tissue that extends the original boundaries of the wound.

Matrix metalloproteinases Zinc-dependent endopeptidases that cleave components of the extracellular matrix and also various other proteins.

Myofibroblast A fibroblast with features of a smooth muscle cell, including contractile properties.

Reactive oxygen species Highly reactive molecules that are formed upon incomplete one-electron reduction of molecular oxygen.

Reepithelialization Coverage of the injured skin with a new epidermis.

Scar Connective tissue replacement following wounding of the dermis.

Ulcer An inflammatory lesion of the skin or a mucous membrane that is characterized by loss of surface tissue, disintegration, and necrosis of epithelial tissue, and often pus.

Molecular and Cellular Biology of Normal Wound Healing and Scar Formation

Injury to the skin of adult mammals rapidly initiates a complex and well-coordinated series of events that ultimately result in repair of the wounded tissue. The wound healing process involves three major phases, which are partially overlapping. They include (1) formation of a blood clot and initiation of an inflammatory response, (2) formation of new tissue, including repair of the injured epidermis (reepithelialization) and replacement of the injured dermis with new

tissue (granulation tissue formation) and finally (3) tissue remodeling ([Figures 1–3](#)). Here we describe the different events that occur during these phases in a normally healing wound, and we also mention what goes awry in impaired and/or excessive wound healing. Finally, we describe the interesting parallels between wound healing and cancer development.

Blood Clotting and Inflammation

Shortly after an injury that comprises the epidermis and the dermis and thus involves vascular damage, a platelet plug and

Figure 1 Schematic representation of an early skin wound in the phase of blood clotting and inflammation. Shortly after injury, blood clot formation prevents excessive bleeding. The clot also serves as a transient barrier and provides a matrix for the invasion of immune cells from the circulation and for migration of resident cells from the wound edge. Several immune cells subsequently invade into the clot. They secrete mediators, which are important for antimicrobial defense and which also initiate reepithelialization and granulation tissue formation. Major cytokines and growth factors orchestrating this phase are indicated.

Figure 2 Schematic representation of a skin wound in the phase of new tissue formation. Three to ten days after wounding, different immune cells are present in the wound granulation tissue and massive angiogenesis occurs. Fibroblasts from the wound edge or fibroblast precursor cells from the bone marrow migrate into the wound. They proliferate and deposit extracellular matrix proteins, and many of them differentiate into contractile myofibroblasts. Keratinocytes from the injured epidermis and hair follicles at the wound edge migrate along the injured dermis and above the provisional matrix. Subsequently, hyperproliferation of the keratinocytes behind the migrating tongue occurs. Major cytokines and growth factors orchestrating this phase are indicated.

Figure 3 Schematic representation of a skin wound in the phase of tissue remodeling. One to two weeks after injury, wound reepithelialization is completed and the keratinocytes redifferentiate and reestablish an efficient barrier. Concomitantly, the cellular density of the granulation tissue gradually declines and the extracellular matrix is remodeled. This results in formation of a scar with reduced tensile strength and elasticity and lack of all appendages. TGF- β is considered as the major regulator of scar formation.

a blood clot are formed that prevent excessive and prolonged bleeding, severe water loss, contamination of the wound with microorganisms and access of toxic compounds to the injured skin. The clot consists mainly of cross-linked fibrin and plasma-derived fibronectin that is released upon injury of blood vessels, but it also includes some additional proteins such as vitronectin and thrombospondins. Furthermore, it is an important reservoir of various cytokines and growth factors that are required for the healing process, and it acts as a matrix for different cell types that are attracted to the wound from the adjacent normal skin or from the circulation (Figure 1; Martin, 1997; Gurtner *et al.*, 2008).

Inflammatory cells are then attracted to the wound site by factors produced upon complement activation or bacterial degradation or which are released from degranulation of platelets. Data from lower organisms, including *Drosophila* and zebrafish, revealed that production of hydrogen peroxide at the wound site via the action of NADPH oxidases also contributes to inflammatory cell recruitment immediately after injury (Niethammer *et al.*, 2009; Moreira *et al.*, 2010). Although a role of hydrogen peroxide in the attraction of immune cells has not been demonstrated yet for mammals, the high conservation of this process among other species and the strong expression of NADPH oxidases at the wound site in mammals, also suggest a contribution of reactive oxygen species (ROS) to the inflammatory response in mammalian wounds. At later stages of the wound healing process, chemokines/cytokines produced and/or released by various cells in the wounded tissue are particularly important for the attraction of immune cells (Figure 1). The first cells that arrive at the wound site are neutrophils due to their abundance in the circulation. They are followed by monocytes that subsequently differentiate into dendritic cells or tissue macrophages. Plasmacytoid dendritic cells (pDCs), which are specialized type I interferon-producing cells, were recently found to infiltrate mouse and human skin wounds 24 h after injury (Gregorio *et al.*, 2010). In response to nucleic acids released from damaged cells, pDCs transiently produce type I interferons and interleukin (IL)-6, and they

induce the expression of IL-17 and IL-22 in T cells, thereby promoting the inflammatory response as well as wound reepithelialization. The invasion of immune cells, in particular during the early phase of repair, is facilitated by the vasodilation and high vascular permeability that is seen in early wounds. This vascular phenotype results at least in part from histamine that is released upon degranulation of mast cells at the wound edge after injury (Figure 1). While mast cells are obviously activated adjacent to the wound, they are only recruited into the wound tissue during the late phase of the repair process (Antsiferova *et al.*, 2013; Willenborg *et al.*, 2014).

The attraction of neutrophils is particularly important for the defense against invading microorganisms, since these cells are a potent source of ROS and of proteins that help to defend microorganisms, in particular proteinases (Figure 1). However, they are not required for the normal wound healing process under sterile conditions, and a prolonged presence of neutrophils results in tissue damage and subsequent impairment of healing. Consistent with this assumption, high neutrophil content is a hallmark of chronic, non-healing ulcers (Martin and Leibovich, 2005; Eming *et al.*, 2007a).

In contrast to neutrophils, there is strong evidence for an important role of macrophages in the control of different stages of the healing process in adult mammals, and their presence is likely to be essential for the healing of large skin defects. Like neutrophils, they are required for the defense against invading microorganisms through their capacity to secrete proteinases and ROS and through their potent phagocytic function. Furthermore, they are a rich source of cytokines and growth factors. Interestingly, however, small wounds were shown to heal in the absence of neutrophils and macrophages under sterile conditions and the quality of the healed tissue was even improved. The most likely explanation for this beneficial effect is the reduced production of toxic products such as ROS in the absence of these innate immune cells, resulting in reduced cell damage. Healing of larger wounds, however, seems to depend on the release of growth factors by macrophages, which stimulate angiogenesis as well as

migration and proliferation of fibroblasts and keratinocytes (Martin and Leibovich, 2005; Eming *et al.*, 2007b).

An important role of mast cells for normal wound healing has been suggested by several studies. However, these experiments were performed with mast cell-deficient mice, which have additional abnormalities due to the lack of a functional c-Kit receptor. The recent generation of mast cell-deficient mice with wild-type c-Kit, which do not reveal any other abnormalities under unchallenged conditions, allowed a more precise analysis of mast cell function in wound healing. Surprisingly, these studies revealed that mast cells are dispensable for the healing of full-thickness excisional wounds in adult mice (Antsiferova *et al.*, 2013; Willenborg *et al.*, 2014).

In contrast to innate immune cells, little is known about the role of adaptive immune cells (B and T lymphocytes) in wound repair. The number of T cells increases in the granulation tissue within a few days after injury and their numbers remain elevated during the late stage of new tissue formation. Recent studies revealed a potential role of these cells in granulation tissue remodeling and scarring, mediated via IL-4, IL-13 and monocyte chemoattractant protein 1 (MCP-1) (Figure 2; Wong *et al.*, 2011), but the responsible T cell subsets remain to be identified. Furthermore, it is as yet unclear if and how these cells are involved in the healing process. The only exception is epidermal $\gamma\delta$ T cells, for which a role in wound reepithelialization has previously been demonstrated through their production of keratinocyte mitogens (Havran and Jameson, 2010).

The Phase of New Tissue Formation

Reepithelialization of skin wounds

The release of chemokines, cytokines, and growth factors by degranulating platelets, invading immune cells, and resident cells at the wound edge initiates the formation of new tissue. This phase starts within 1–2 days after injury by collective and coordinated migration of keratinocytes from the epidermis and injured hair follicles at the wound edge into the wounded area. Keratinocytes at the epidermal fronts initially attach to the exposed collagen and migrate down the injured dermis. Upon formation of granulation tissue they change their expression of integrin receptors, allowing them to attach to and to migrate on the newly deposited matrix proteins of the granulation tissue. To allow efficient migration, keratinocytes at the wound edge rearrange their cytoskeleton and extend lamellipodia. They reduce and modify their cell–cell contacts and the hemidesmosomes that allow them to attach to the basement membrane (Martin, 1997; Gurtner *et al.*, 2008). In addition, they secrete various types of proteinases to allow degradation of the connective tissue. These include plasminogen, which degrades the fibrin matrix, and different matrix metalloproteinases (MMP) (Figure 2). Consistent with the important function of these enzymes in wound healing, plasminogen-deficient mice showed strongly impaired reepithelialization, and healing was completely inhibited when wounds in these mice were treated with a broad-spectrum MMP inhibitor (Lund *et al.*, 1999).

The cellular alterations that occur at the migrating front of the wound epidermis are reminiscent of epithelial-

mesenchymal transition (EMT), a process that occurs during embryonic development and also in malignant carcinomas. During EMT, epithelial cells transdifferentiate into migratory individualized cells with a fibroblast-like morphology. In addition, they lose their epithelial cell markers and acquire markers characteristic for mesenchymal cells, such as the cytoskeletal protein vimentin. However, a complete EMT as seen in various cancer cells does not occur in keratinocytes of skin wounds. Rather, these cells retain some intercellular junctions and therefore show collective migration, and they still express epidermal keratins, but not vimentin. While keratinocyte migration is sufficient for the reepithelialization of small wounds, a wave of keratinocyte hyperproliferation, that occurs in keratinocytes behind the leading edge, is essential to replenish a larger wounded area with new epithelial cells. Reepithelialization is activated by various growth factors and cytokines. Functional studies in mouse models have revealed particularly important roles of hepatocyte growth factor (HGF) and of members of the fibroblast growth factor (FGF) and epidermal growth factor (EGF) families in keratinocyte migration and/or proliferation in wounded skin, although several other factors are also involved (Gurtner *et al.*, 2008; Schafer and Werner, 2008a; Figure 2).

Formation of granulation tissue

Shortly after the onset of reepithelialization, repair of the injured dermis is initiated, resulting in formation of the so-called granulation tissue (Figure 2). This is a highly vascularized and cell-rich tissue, which gradually replaces the fibrin clot. The name granulation tissue results from its granular appearance due to the presence of multiple nuclei. Initially, fibroblasts from the dermis at the wound edge are attracted to the wound site and they also start to proliferate. In addition hematopoietic stem cells and mesenchymal stem cells from the bone marrow are attracted to the wound tissue where they differentiate into collagen-producing fibroblasts (Gurtner *et al.*, 2008). Of particular importance for wound healing are fibrocytes, which are blood-borne cells expressing markers of hematopoietic and stromal cells. These cells differentiate into fibroblasts and myofibroblasts (see below) and they contribute to wound healing and pathological fibrosis (Wu *et al.*, 2007).

Activated fibroblasts in the dermis at the wound edge and in the granulation tissue produce growth factors that regulate wound reepithelialization in a paracrine manner, including HGF as well as EGF and FGF family members. In addition, they secrete proteinases to degrade the initial fibrin matrix and they produce the vast majority of the novel extracellular matrix proteins (ECM), including collagen type III, fibronectin, tenascin C, as well as proteoglycans and glycosaminoglycans. One of the major factors involved in the regulation of fibroblast migration and proliferation in skin wounds is platelet-derived growth factor (PDGF), which is initially released from degranulating platelets. During the healing process it is produced by several cell types, in particular by keratinocytes, and therefore it acts in a paracrine manner to stimulate migration, proliferation and matrix deposition by fibroblasts (Werner and Grose, 2003). Another major regulator of fibroplasia is TGF- β , which is also released from platelets. Subsequently, TGF- β is produced by many cell types in the healing wound. Furthermore, in combination with ED-A fibronectin, a splice variant

of fibronectin that is produced in wounded skin, and mechanical tension, TGF- β induces the differentiation of a large percentage of the wound fibroblasts into myofibroblasts. These cells express alpha-smooth muscle actin and therefore have efficient contractile properties. Thus, they are strongly involved in the contraction of the wound. In addition, they produce particularly large amounts of extracellular matrix proteins and they secrete proteinases, which mobilize growth factors from the matrix and which orchestrate the remodeling of the newly formed connective tissue (Tomasek *et al.*, 2002).

In parallel to the migration and proliferation of fibroblasts, new blood vessels are formed in the granulation tissue. This is essential for the supply of the cells with oxygen and nutrients (Figure 2). Neovascularization in skin wounds is mainly achieved by angiogenesis, the sprouting of new vessels from preexisting vessels. Bone marrow-derived endothelial progenitor cells can also be incorporated into new wound vessels, in particular under ischemic conditions, but their contribution to vessels in normally healing wounds appears minor. Blood vessels in wounds are initially leaky due to the presence of factors that induce vascular permeability, such as histamine and vascular endothelial growth factor A (VEGF-A). This results in continuous deposition of plasma-derived matrix proteins during the early phase of healing. Several days after healing, most of the vessels have lost the initial hyperpermeability and they become stabilized through association with pericytes and smooth muscle cells (Eming *et al.*, 2007a).

Several growth factors orchestrate the formation of new blood vessels in skin wounds. Of particular importance is VEGF-A, which is upregulated in response to the severe hypoxia that is present in early wounds. This involves hypoxia-induced stabilization of the transcription factor hypoxia-inducible factor 1 α . In addition, the related placental growth factor as well as members of the FGF family, in particular FGF2, are involved in wound angiogenesis. The subsequent stabilization of immature vessels by pericytes and smooth muscle cells is mainly achieved by angiopoietin-1 in combination with PDGF. Following the onset of blood vessel formation, lymphangiogenesis occurs in the granulation tissue to reconstruct the lymphatic vasculature. This process is predominantly controlled by VEGF-C and VEGF-D (Muller *et al.*, 2012).

Finally, nerve sprouting occurs at the wound site, resulting in reinnervation of the injured tissue. The wound is initially hyperinnervated, but this reverts during the remodeling phase (see below). Interestingly, reinnervation is important for normal wound healing as demonstrated by the severe healing impairments upon inhibition of this process (Werner and Grose, 2003).

The Phase of Tissue Remodeling

Following the phase of new tissue formation, the proliferation rate of keratinocytes returns to that of normal skin and the keratinocytes of the neo-epidermis redifferentiate, resulting in re-establishment of the epidermal barrier. At this stage the epidermis gets firmly attached to the underlying late granulation tissue/early scar tissue through reformation of the basement membrane and of hemidesmosomes, which

mediate this attachment (Figure 3). The factors, which control the shut-down of epidermal repair and the re-establishment of the keratinocyte differentiation program are still largely unknown, but members of the TGF- β superfamily and downstream effectors are likely to be involved.

In parallel to the maturation of the epidermis, remodeling of the granulation tissue is initiated, which can last up to several months. During this process the high cellularity of the granulation tissue is reduced due to apoptosis of (myo)fibroblasts and endothelial cells, resulting in vessel regression. This is most likely a consequence of the decrease in the levels of angiogenic growth factors. Since many of them are produced by macrophages, the reduction in the number of these immune cells due to apoptosis or reentry into the circulation may well contribute to vessel regression. In addition, alterations in the proteinase expression profile and the replacement of the provisional matrix by mature collagen are likely to play a role in this process. As a consequence of these apoptotic processes, the resulting scar tissue has a very low cellularity and it is mainly composed of connective tissue (Gurtner *et al.*, 2008; Figure 3).

The extracellular matrix of the granulation tissue/scar tissue undergoes a particularly extensive and long-lasting remodeling process. It involves a switch from production of collagen type III to collagen type I, which enhances the tensile strength. In addition, alterations in collagen cross-linking occur and the new fibers are aligned along tension lines. Finally, the balance between production and degradation of extracellular matrix is shifted toward the latter due to the enhanced expression of various MMPs. During the remodeling process, the tensile strength of the tissue increases continuously, but it never exceeds 70–80% of values of non-wounded skin. The elasticity of the new tissue is also significantly lower due to the lack of elastic fibers. Finally, the resulting scar tissue lacks hair follicles, sebaceous glands and sweat glands, which cannot regenerate (Gurtner *et al.*, 2008; Figure 3).

All wounds that involve dermal injury heal with a scar. The latter are normally flat and restricted to the initial wound area. However, scarring can be excessive, resulting in hypertrophic scars that are still restricted to the original wound site or keloids, which can strongly exceed this area. Hypertrophic scars and keloids are characterized by a prolonged presence of (myo)fibroblasts, which produce excessive amounts of connective tissue and by abnormal organization of collagen fibres. TGF- β is considered as the most important regulator of scarring, although additional factors contribute to this process, including activin and osteopontin. Furthermore, recent studies revealed that mechanical tension promotes scar formation through induction of Th2 cytokines and inflammatory chemokines (Wong *et al.*, 2011).

Importantly, mammalian embryos show scarless healing up to the end of the second trimester. Although not fully understood, the lack of scar formation in early embryos is thought to result from a limited inflammatory response compared to healing in adults, from reduced expression of TGF- β , as well as from differences in the proteinase expression profile. In the future it will be important to understand the cellular and molecular differences between wound healing in adults and embryos. This will be a prerequisite for the development of strategies that prevent scar formation in adults.

Figure 4 Cellular parallels between a malignant skin cancer and a healing skin wound. An epithelial cancer is shown schematically. Note the remarkable parallels to a skin wound in the phase of new tissue formation (Figure 2). Similar to granulation tissue of skin wounds, the tumor stroma includes different types of immune cells, newly formed blood and lymphatic vessels, and a large number of (myo)fibroblasts. In addition, hyperproliferating keratinocytes are present in the wound and in the cancer tissue. The major difference between a malignant tumor and a healing wound is the invasive and uncontrolled growth of the malignantly transformed keratinocytes.

Wound Healing versus Regeneration

While mammals heal their wounds using the above-described repair process that leads to development of scar tissue, some lower organisms, including amphibians, planarians, and hydra, have the capacity to fully regenerate, even after amputation of the head, the limbs and/or the tail. When these animals are severely injured, differentiated cells along the wound site are able to dedifferentiate and they form a so-called blastema. The blastemal cells subsequently proliferate, followed by redifferentiation according to the original lineage upon completion of wound closure. Although part of this regenerative capacity is retained in mammals, the rapid formation of scar tissue most likely prevents efficient and complete tissue regeneration (Tanaka and Reddien, 2011). A recent study, however, demonstrated that certain mammals retain a full regenerative capacity as demonstrated for the African spiny mouse. Shedding of larger skin areas and subsequent tissue regeneration were observed in these animals, involving formation of a blastema-like structure and subsequent regeneration of skin and all appendages (Seifert *et al.*, 2012). These results raise hope that strategies can be developed in humans to unlock such latent regenerative pathways, and it will therefore be important to identify the molecular and cellular mechanisms of the regenerative response of such animals and the differences to healing with scar formation.

process follows the same principles in humans. While wound healing is generally efficient in young patients, the repair capacity declines upon aging. In addition, there are many patients who suffer from severely impaired healing as a result of (1) bacterial infection of surgical or burn wounds, (2) treatment with anti-inflammatory steroids or chemotherapy or (3) systemic disease such as metabolic, vascular or autoimmune disease or a combination of these risk factors. These conditions frequently lead to the formation of chronic non-healing ulcers (Sen *et al.*, 2009). The underlying pathomechanisms are still insufficiently understood, in particular due to the lack of appropriate animal models for chronic wounds. However, vascular abnormalities, reduced levels of active growth factors, or reduced reactivity to these mitogens are suggested to be involved, together with enhanced levels/activities of various proteinases. In addition, the number of neutrophils and macrophages is frequently increased and their presence at the wound site is prolonged, resulting in excessive production of toxic ROS (Schafer and Werner, 2008b; Sindrilaru *et al.*, 2011). Future studies are required to gain insight into the molecular and cellular mechanisms underlying the pathogenesis of different types of chronic wounds. This will be a prerequisite for the development of improved therapeutic strategies.

Parallels between Wound Healing and Cancer

A dangerous consequence of chronic, non-healing wounds is the increased risk of squamous cell carcinoma development at the wound site, which is thought to result from the chronic inflammation. This association is also seen in various other

Impaired Wound Healing and Clinical Problems

The mechanisms underlying normal wound healing have been most thoroughly characterized in rodents, but the healing

tissues, such as the stomach or the intestine, where chronic inflammation due to the infection with *Helicobacter pylori* or the presence of inflammatory bowel disease, respectively, increases the risk of cancer development. These clinical observations as well as several experimental studies in mice suggested that common cellular and molecular mechanisms are active in wounds and in malignantly transformed tissues, and it was suggested by Dvorak (1986) that “cancers are wounds that do not heal.” In recent years, this hypothesis has been strongly supported by results from various studies that revealed strong cellular parallels between wound healing and cancer, including enhanced cell migration and proliferation, inflammation, angiogenesis, lymphangiogenesis, deposition of a similar type of matrix as well as fibrosis (Schafer and Werner, 2008a; Figure 4). Parallels between wound healing and cancer are also seen at the molecular level, since the gene expression profile of healing skin wounds shows strong similarities with the gene expression profile of carcinomas. Most interestingly, the presence of a gene expression signature that is similar to the one seen in early wounds allows a prediction of poor prognosis (Schafer and Werner, 2008a). In spite of these impressive parallels, a few major differences exist between wounds and tumors, in particular the presence of mutations and epigenetic alterations, which occur in tumors and prevent the temporal and spatial limitation of cell proliferation characteristic for wounded skin. In the future, it will be important to identify these differences in order to selectively inhibit tumor growth without affecting the wound healing process.

Cancer Cell Invasion through Tissue Barriers

M Santiago-Medina, T Palmer, and J Yang, University of California, San Diego, CA, USA

Introduction

Metastasis is the most life-threatening aspect of cancer progression and is responsible for around 90% of cancer patient mortality. The metastatic process, in which cancer cells disseminate from their primary sites to form secondary tumors throughout the body, consists of a series of molecularly intricate steps. The initial step of tumor cell dissemination is invasion of the tumor cell into the surrounding tissue. During intravasation, tumor cells enter the circulatory system by breaching blood and/or lymphatic vessels. Subsequently, tumor cells must survive in circulation until they extravasate at a distant site and begin to proliferate. This proliferation at a secondary site can lead to the colonization of an essential organ, resulting in organ failure and ultimately host death.

During each of these intricate steps, cancer cells undergo the necessary cellular changes to adapt to their new environment. By adopting numerous molecular machineries to drive cell migration, invasion, and anti-apoptosis, cancer cells are

able to successfully colonize secondary sites. These processes include the epithelial–mesenchymal transition (EMT) program, which allows cancer cells to dissociate from each other and migrate away from the primary tumor, anoikis resistance, which protects cells from undergoing apoptosis in the absence of sufficient matrix attachment, and the formation of cell protrusions such as invadopodia and microtentacles, which allow cells to attach to and modify the surrounding environment. In this article, we describe the cellular programs involved in cancer cell invasion and metastasis and discuss the most widely accepted findings relevant to each molecular process (Figure 1).

EMT

Benign carcinoma cells are adhered to one another through cell–cell adhesions, such as adherens junctions and desmosomes. In addition, they may also be attached to an underlying

Figure 1 Cancer cell invasion and metastasis. Noninvasive epithelial cancer cells (orange cells) can undergo EMT to become migratory cancer cells (red). Cancer cells can breach the BM via collective cell migration and invasion. A subset of cancer cells can penetrate the BM via invadopodia-mediated ECM degradation. Migrating tumor cells develop resistance to anoikis, thereby allowing them to survive without appropriate ECM attachment. Cells continue to invade their surrounding tissues and intravasate into the systemic circulation via various membrane protrusions, including invadopodia, lamellipodia, and filopodia. CTCs extravasate from the blood circulation via microtentacle-mediated attachment to endothelial cells and then invadopodia-mediated endothelium breaching. In the new tissue microenvironment, cancer cells reverse EMT and proliferate to give rise to macrometastases. BM, basement membrane; EMT, epithelial–mesenchymal transition; McTNs, microtentacles.

basement membrane (BM). To metastasize, cancer cells need to separate from each other and acquire migratory and invasive capabilities. One effective way to achieve this is to activate a cellular process named EMT. During EMT, cancer cells change their adhesion profile, undergo a dramatic reorganization of the actin cytoskeleton, and form specialized membrane protrusions that are required for invasive migration. This process, which normally operates during embryo morphogenesis and wound healing, is usurped by tumor cells to achieve enhanced migration and invasion.

It is important to note that EMT is dynamically regulated during metastasis: turning on EMT promotes invasion and dissemination of tumor cells into distant organs; while turning off EMT is required for the establishment of distant metastasis (Tsai *et al.*, 2012). Furthermore, analyses of human breast cancer-circulating tumor cells suggest that a partial EMT may be sufficient to promote tumor cell dissemination (Min *et al.*, 2009; Kallergi *et al.*, 2011). Furthermore, cancer cells can also accomplish collective cell invasion in the absence of EMT (Wicki *et al.*, 2006).

Triggers of EMT

Carcinoma cells are thought to undergo EMT in response to a combination of intrinsic genetic changes within tumor cells and extracellular signals in the tumor microenvironment. Notably, oncogenic signals, such as Ras activation, have been shown to be required for tumor cells to respond to EMT-inducing extracellular signals. Under different physiological conditions, a number of extracellular signals, including Wnt, Notch, and growth factor receptor signals have been implicated in inducing some aspects of the EMT program. Growth factors known to induce EMT are transforming growth factor β (TGF β), tumor necrosis factor- α (TNF- α)/nuclear factor κ B (NF- κ B), hepatocyte growth factor (HGF), members of the epidermal growth factor (EGF) family, insulin-like growth factor (IGF), fibroblast growth factor (FGF), and platelet-derived growth factor (PDGF) (Acevedo *et al.*, 2007; Tsai and Yang, 2013). Most notably, the TGF-pathway appears to be a primary inducer of EMT under various physiological conditions (Katsuno *et al.*, 2013). In addition to growth factor signaling and inflammatory cytokines, hypoxia in the tumor microenvironment has also been shown to promote EMT (Yang *et al.*, 2008). Changes in extracellular matrix (ECM) composition and density are also known to be involved in EMT induction. Matrix proteins such as collagen I, collagen IV, fibronectin, tenascin C, and hyaluronan have been implicated in EMT activation in certain cell types (Wong and Rustgi, 2013). Studies also suggest that besides the signaling input of these ECM molecules, they may also regulate EMT and invasion by increasing ECM density and rigidity (Levental *et al.*, 2009; Provenzano *et al.*, 2009).

EMT-Inducing Transcription Factors

Although the triggers for EMT are very diverse, these upstream pathways converge onto a key group of EMT-activating transcription factors. These EMT-inducing transcription factors include the Snail family of zinc-finger transcription factors

Snail1/Snail2, the Zeb family of transcription factors Zeb1/Zeb2, and the Twist family of bHLH transcription factors Twist1/Twist2. In response to a myriad of microenvironmental stimuli, they function together as master molecular switches of the EMT program. Importantly, many of these transcription factors can induce each other in a positive feedback loop to coordinately orchestrate the entire EMT program.

Mechanistically, the Snail and Zeb family of EMT transcription factors are capable of directly binding to the E-boxes of the E-cadherin promoter, recruiting transcriptional corepressors and histone deacetylases to repress its transcription (Batlle *et al.*, 2000; Hajra *et al.*, 2002). The Zeb family proteins are also able to suppress E-cadherin transcription (Comijn *et al.*, 2001) via a double-negative feedback loop controlling Zeb1/Zeb2 and miRNA-200 family expression (Bracken *et al.*, 2008; Korpai *et al.*, 2008; Park *et al.*, 2008). Both the Snail and Zeb family of transcription factors also repress the expression of other cellular junction proteins, such as claudins and ZO-1 (Ohkubo and Ozawa, 2004; Vandewalle *et al.*, 2005). The Twist family of transcription factors, including Twist1 (Yang *et al.*, 2004) and Twist2 (Fang *et al.*, 2011) can induce EMT. Twist1 not only represses E-cadherin through induction of Snail transcription factors (Yang *et al.*, 2004; Casas *et al.*, 2011), but it also activates programs associated with tumor invasion (Eckert *et al.*, 2011), thus coordinating two major aspects of the EMT program.

As mentioned above, a subset of these alterations in EMT-transcription factor signaling can be regulated via miRNAs. Moreover, several regulatory circuits involving microRNAs (Bullock *et al.*, 2012), epigenetic machinery (Tam and Weinberg, 2013), and posttranslational control (De Craene and Berx, 2013) are crucial in enabling cancer cells to maintain a plastic cellular state or switch between the epithelial and mesenchymal states. For example, additional miRNAs that regulate EMT include miR-9 and miR-30a, which targets the E-cadherin-encoding mRNA CDH1 and Snail, respectively (Ma *et al.*, 2010; Kumarswamy *et al.*, 2012).

EMT-Associated Cellular and Molecular Changes

During EMT, epithelial cells undergo extensive morphological and cellular changes to adopt mesenchymal cell characteristics. Many of the hallmark EMT markers are subcellular structure proteins that define the epithelial or mesenchymal identity of a cell. Among them, E-cadherin is regarded as a gatekeeper of the epithelial state in various epithelial cell types. Snail and Zeb family of EMT transcription factors can directly suppress E-cadherin transcription as discussed above. Down-regulation of E-cadherin can also occur at the posttranslational level due to the activation of proteases, which cleave the protein and lead to its removal from the plasma membrane (Marambaud *et al.*, 2002; Maretzky *et al.*, 2005). Very often, in cell culture, down-regulation of E-cadherin is accompanied by the increased expression of N-cadherin, a phenomenon called the cadherin switch (Wheelock *et al.*, 2008). Additionally, other genes important in the maintenance of epithelial cell-cell adhesion such as the tight junction proteins, claudins and occludin, and the desmosome proteins, desmoplakin and plakophilin, are also repressed during this transition (Lamouille *et al.*, 2014).

Similarly, up-regulated genes include those encoding proteins involved in cell migration and invasion, such as the intermediate filament protein vimentin, and the ECM proteins fibronectin and collagen I. Importantly, through this transition, cells lose their association with epithelial cells and acquire the ability to interact and modify the surrounding ECM, thus facilitating cell migration and invasion.

Cancer progression is marked by an increase in the deposition and cross-linking of fibrillar ECM components, such as collagen and fibronectin, which results in an increase in ECM density and cell–matrix adhesions. Mirroring the cadherin switch, there are similar changes in the expression and activation of pro-invasive integrins induced by EMT-inducing transcription factors. This switch in the adhesion profile of carcinoma cells is what allows tumor cells to adhere and venture into novel territory while evading apoptosis or other cell growth inhibiting signaling pathways. As epithelial cells differentiate into mesenchymal cells, they exchange their BM-binding integrins for integrins that adhere to the surrounding collagen I-rich ECM, thus enhancing their ability to migrate away from the epithelium and invade into surrounding tissues. Migration-promoting integrins, including $\alpha1\beta1$, $\alpha2\beta1$, and $\alpha5\beta1$ are activated during EMT and increase cell adhesion to fibronectin and collagen I (Friedl and Alexander, 2011). Increased activation of mesenchymal integrins and their interactions with ECM proteins can also facilitate the disruption of E-cadherin complexes, while inducing N-cadherin expression (Koenig *et al.*, 2006; Shintani *et al.*, 2008). Other integrins associated with EMT, invasion and metastasis as well as poor prognosis in patients include $\alpha V\beta6$ (Bandyopadhyay and Raghavan, 2009) and $\alpha6\beta4$ (Evans *et al.*, 2003). Furthermore, changes to the integrin repertoire during EMT can lead to increased expression of proteases, such as the matrix metalloproteinases MMP2 and MMP9, which in turn stimulate cell migration and invasion into tissues. Studies have reported that colocalization and cooperation between $\beta1$ - and $\alpha V\beta3$ -integrin with MT1-MMP regulates cell invasion into the surrounding ECM (Galvez *et al.*, 2002).

Invadopodia

Carcinoma *in situ* are surrounded by thin, dense, and highly cross-linked ECM known as the BM. Comprised primarily of the macromolecules collagen IV and laminin and to a lesser extent perlecan and nidogen/entactin, the BM is a thin (~100 nm thick), but mechanically strong barrier. Carcinoma cells invade into nearby tissues and disseminate into the circulation by breaching through the underlying BM and surrounding ECM. Instead of using secreted MMPs, tumor cells actively remodel the ECM through the use of specialized subcellular structures termed invadopodia. Invadopodia are actin-based membrane protrusions located on the basal surface of cells at the cell–matrix interface. In two-dimensional (2D) settings, invadopodia appear as long-lived F-actin puncta with half-lives ranging from minutes to hours. Common molecular components of invadopodia include many of the same actin-regulatory proteins found in lamellipodia and filopodia, such as Arp2/Arp3, cofilin, cortactin, and WASP. As sites of cell adhesion, they also contain integrin receptors, Src,

PIXN, and FAK (Chan *et al.*, 2009). The RhoGTPase, Cdc42, and the scaffolding protein, Tks5, are thought to be crucial components for the assembly and degradation ability of invadopodia, respectively (Di Martino *et al.*, 2014). Invadopodia regulate tumor invasion by both adhering to and digesting the underlying ECM, thus allowing tumor cells to penetrate and migrate into the ECM.

BM Breach, Intravasation, and Extravasation

Studies performed both *in vitro* and *in vivo* have demonstrated a role for invadopodia-mediated BM breach. In *in vitro* assays, carcinoma cells cultured on intact BMs utilize invadopodia to degrade the matrix and subsequently assist the cell in crossing the membrane barrier (Schoumacher *et al.*, 2010). In *Caenorhabditis elegans*, the anchor cell forms a series of invadopodia-like structures, which are required for the cell to traverse the BM between cell tissues (Lohmer *et al.*, 2014).

Once metastatic tumor cells have successfully degraded their way to and through a BM, they may enter a blood vessel or lymphatic vessel through a process known as intravasation. During this process, cells enter the circulatory system by pushing and degrading their way through the BM and endothelial cell barrier that comprises the vessel. The mechanism in which carcinoma cells bypass the endothelial barrier to gain entry into circulatory vessels is known as transendothelial migration. Importantly, invadopodia have also been implicated in intravasation and metastasis *in vivo* (Gligorijevic *et al.*, 2014; Roh-Johnson *et al.*, 2014). To exit circulation, circulating tumor cells (CTCs) attach to the endothelial cells that coat the luminal side of the blood vessel and begin a process termed extravasation. As with intravasation, invadopodia also mediate extravasation and subsequent metastasis (Leong *et al.*, 2014; Sutoh Yoneyama *et al.*, 2014).

Invadopodia Induction

During EMT, epithelial cells breach the BM and migrate through the ECM by provoking the formation of invadopodia-like structures. The EMT transcription factor, Twist1, promotes invadopodia formation in response to various EMT-inducing signals (Eckert *et al.*, 2011). Likewise, a number of EMT-inducing cues are also implicated in the formation of invadopodia. For example, both EMT and invadopodia formation can be stimulated by various growth factors, including EGF (Yamaguchi *et al.*, 2005), HGF (Rajadurai *et al.*, 2012), PDGF (Eckert *et al.*, 2011), and TGF β (Pignatelli *et al.*, 2012). Additionally, environmental stimuli associated with EMT such as hypoxia, acidic pH, and matrix stiffness also promote the formation and activity of invadopodia (Alexander *et al.*, 2008a; Lucien *et al.*, 2011; Diaz *et al.*, 2013). These chemical and physical stimuli converge onto the activation of Src kinase and Rho GTPases, which are required in invadopodia formation.

Assembly of Invadopodia

Invadopodia appear as actin-rich puncta which at times are surrounded by a ring of adhesion proteins (Branch *et al.*, 2012). The formation of invadopodia follows a sequence of

distinct steps, beginning with an immature structure known as an invadopodium precursor. Invadopodium precursors begin with the local enrichment of actin and cortactin at sites of cell–ECM contact. This is followed by the recruitment of Tks5 as well as a change in the lipid composition of the plasma membrane at sites of maturing invadopodia (Sharma *et al.*, 2013). This change in lipid identity creates a docking site for Tks5, thus stabilizing the invadopodium precursor. Once stable, the invadopodium recruits proteases that mediate pericellular degradation, thus forming a fully functional mature invadopodium. One such protease, MT1-MMP, has been shown to be transported continually to mature invadopodia via recycling of endosomal vesicles (Hoshino *et al.*, 2012).

In three-dimensional (3D) matrices, invadopodia take on a different manifestation than their characteristic dot-like appearance in 2D. Invadopodia capable of forming stable 3D-structures appear as long, thin protrusions (Beatty *et al.*, 2013). Importantly, invadopodia of 3D environments maintain the same molecular signature and proteolytic function for invasion as their 2D counterparts (Yu and Machesky, 2012). In addition to 3D cell culture systems, an increasing number of recent studies have begun to characterize these structures under physiologic settings *in vivo*. For example, invadopodia-mediated cell invasion has been studied in dermis-based matrix (Tolde *et al.*, 2010), in organogenesis models of *C. elegans* (Lohmer *et al.*, 2014), and recently, in developing spinal cord neurons (Santiago-Medina *et al.*, 2015). Together, these data suggest a critical role for invadopodia in ECM degradation and remodeling in various physiological settings.

Modes of Cell Migration

To invade and metastasize successfully, cancer cells must be extremely versatile, capable of employing multiple cellular mechanisms to migrate during the metastatic process. These include mesenchymal cell migration, collective cell migration, and protease-independent amoeboid migration.

Mesenchymal Migration

During the progression of EMT, a high-degree of actin remodeling takes place. The onset of cell motility requires a relaxation of static actin structures to form dynamic membrane protrusions. In epithelial cells, actin filaments are organized in thin cortical bundles. This is contrary to mesenchymal cells, in which the actin is bundled into thick contractile stress fibers at the ventral cell surface. During cell migration, rigid actin stress fibers are disassembled and polymerized into a cortical actin meshwork, from which cell membrane protrusions like lamellipodia and filopodia emerge. Lamellipodia are flat, sheet-like protrusions composed of both unbranched and branched actin filaments. Filopodia are thin bundles of actin filaments that emanate into the surrounding environment from the leading edge. The formation of both lamellipodia and filopodia not only assist tumor cells physically migrating from one point to another, but also serve as exploratory structures that sense molecular cues in the microenvironment during the metastatic process. Actin-regulatory proteins such as Arp2/Arp3, Ena-Vasp, WASP, mDia, and cortactin are

redistributed within cells to produce these new membrane protrusions. Indeed, the increased expression of these actin-regulatory proteins correlates with poor prognosis in breast and liver carcinomas (Iwaya *et al.*, 2007). Additionally, these actin-based membrane protrusions are known to secrete proteases such as MMPs and ADAMs, revealing their potential role for the onset of cell invasion (Machesky, 2008).

The remodeling of the actin cytoskeleton that occurs during carcinoma cell migration and invasion depends on the activation of a family of molecular switches known as Rho GTPases. RhoA, Rac1, and Cdc42 are best studied among the 23 family members of Rho GTPases. With regard to migration and invasion and in a simplified view, RhoA induces actin stress-fiber formation and regulates cytoskeletal changes affecting cell–cell or cell–matrix adhesion, Rac1 is involved in lamellipodia and membrane ruffle formation, and Cdc42 is involved in filopodia formation. Based on their function in integrating and transmitting signals from chemokine, growth factor receptors and integrin-ECM binding onto the remodeling of the actin cytoskeleton, Rho proteins play a critical role in facilitating mesenchymal cell migration.

Amoeboid Migration

In addition to protease-based mesenchymal migration, tumor cells display amoeboid movement that does not require protease-mediated ECM remodeling. Amoeboid migration is characterized by cycles of expansion and contraction of the cell body and membrane blebbing mediated by Rho/ROCK-mediated actomyosin contractility. Tumor cells that adopt amoeboid migration display a characteristic rounded shape when observed in 3D matrices. This enables the cells to squeeze through preexisting gaps in ECM fibers as well as to exert sufficient force to deform the surrounding ECM without activating ECM degradation pathways.

Importantly, amoeboid and mesenchymal forms of invasion are two modes of migration that invading cells may use interchangeably as seen during mesenchymal–amoeboid transition (MAT) or amoeboid–mesenchymal transition (AMT). The low-adhesion attachment to the substrate enables amoeboid cells to translocate in the 3D environment at relatively high velocities, reaching up to $25 \mu\text{m min}^{-1}$ (Friedl *et al.*, 1994). Amoeboid cell migration can serve as a compensatory mechanism of migration upon inhibition of pericellular proteolysis.

Collective Cell Migration

Many types of epithelial cancers, including breast, prostate, pancreatic, and lung cancer, display a multicellular form of migration known as collective cell invasion. Such multicellular units consist of cells that migrate together during invasion into the surrounding stroma as well as during intravasation and metastasis. The cells comprising these mobile clusters remain bound to one another by expressing cell–cell junction molecules such as cadherins, tight junction proteins, adhesion receptors of the immunoglobulin superfamily, and gap junctions. In addition to providing cell–cell adhesion, the aforementioned junction molecules also maintain what are known as supracellular properties. These include multicellular

front–rear polarity, cytoskeletal synchronization, and juxtacrine cell–cell signaling (Friedl and Gilmour, 2009). The degree of cell–cell adhesion, cell–matrix adhesion and proteolysis can vary among cell groups giving rise to various subtypes of collective invasion (Friedl *et al.*, 2012). As a result, invading cell groups can appear as strands, monolayer sheets, or masses that form luminal structures. Cells at the periphery of the cell mass as well as at the leading edge generate traction force by actomyosin-mediated protrusion and contractility. The cells situated at sites of ECM contact engage in integrin signaling while matrix-degrading proteases, such as MT1-MMP mediate proteolytic ECM remodeling to widen tissue space during migration (Friedl and Gilmour, 2009).

Different *in vitro* models have been used to study the mechanisms of collective cell migration such as the widely used scratch-wound assay as well as tumor explants cultured in 3D matrices. By injecting 3D spheroids into the deep dermis of mice that were monitored through a window chamber, collective cell invasion has also been assessed *in vivo* (Alexander *et al.*, 2008b). Additional *in vivo* evidence for collective cancer cell invasion includes the histopathological analysis of human cancer lesions, in which neoplastic multicellular strands and masses cross tissue boundaries and extend into the stroma (Christiansen and Rajasekaran, 2006). Recent studies having found tumor cell clusters in the circulation of cancer patients suggest that collective cell invasion may also occur during intravasation (Hart, 2009; Hou *et al.*, 2011).

Anoikis

After entering the circulatory system, tumor cells in suspension must survive the lack of proper ECM attachment and the shear stresses of the vascular circulation to reach distant tissues. In the absence of cell attachment to an ECM or upon cell adhesion to an inappropriate location, normal cells undergo a specific type of apoptosis, termed anoikis (from the Greek for ‘homelessness’). In adherent cells, the activation of integrins and their downstream signaling mediators, including the non-receptor tyrosine kinase Src, FAK, and integrin-linked kinase (ILK), provide protection from anoikis (Guadamillas *et al.*, 2011). In the absence of these adhesion-based signals, cells activate caspases and endonucleases, leading to DNA fragmentation and cell death. Cancer cells are able to bypass this safeguard, and as a result, survive under suspension conditions or proliferate at ectopic sites where ECM proteins are different from the cells’ native ones. Indeed, CTCs clearly show resistance to anoikis (Yu *et al.*, 2011). This deregulation in anoikis execution is another hallmark of cancer cells and contributes to metastasis.

Cancer cells develop anoikis resistance by implementing several distinct mechanisms, including the up-regulation of integrin signaling, activation of inside–out pro-survival signals, overexpression of growth factor receptors, and activation of oncogenes. The tumor microenvironment can also contribute to anoikis resistance by modulating matrix stiffness, enhancing oxidative stress, producing pro-survival soluble factors, as well as by triggering EMT and a self-renewal ability. Carcinoma cells can avoid succumbing to anoikis by altering their integrin repertoire. For example, in squamous cell

carcinoma, a switch from $\alpha v\beta 5$ integrins to $\alpha v\beta 6$ integrins induces the intrinsic apoptotic pathway when uncoupled, and activates the pro-survival phosphoinositide 3-kinase (PI3K)–Akt pathway, respectively (Janes and Watt, 2004). Additional examples include down-regulation of $\alpha v\beta 3$ in intestinal carcinoma cells as well as up-regulation of $\alpha v\beta 3$ in melanoma cells, which suppress anoikis by modifying the anti-apoptotic Bcl-2 and pro-apoptotic Bax proteins (Paoli *et al.*, 2013).

Another mechanism employed by tumor cells to overcome anoikis is the hyperactivation of growth factor pathways and receptor tyrosine kinases (RTKs). Detached tumor cells silence the requirement for integrin signaling by constitutively activating pro-survival cascades, such as PI3K, Ras–Erk, NF- β B, and RhoGTPase signaling (Tsuji *et al.*, 2009). This is achieved through autocrine secretion of many of the same growth factors implicated in EMT, such as FGF, HGF, and PDGF. Additionally, overexpression of RTKs, such as EGFR, TrkB, HGF, and ErbB2 receptors also lead to the suppression of anoikis in tumor cells (Guadamillas *et al.*, 2011).

Downstream of RTKs, detached or migrating cancer cells modulate the PI3K–Akt pathway to compensate for the loss of integrin signals and overcome anoikis. This pathway integrates most of the pro-survival signals derived from integrins and growth factors receptors. Sustained Akt activation is achieved as a consequence of an alteration in PI3K activity, constitutive activation of receptor protein tyrosine kinases, activating Ras mutations, and loss of PTEN tumor suppressors (Guadamillas *et al.*, 2011). Interestingly, Akt activation also occurs following the switch from E-cadherin to N-cadherin that takes place during EMT. N-cadherin recruits PI3K which in turn activates Akt and induces anoikis resistance (Cavallaro and Christofori, 2004). Depletion of E-cadherin promotes mammary cell survival following loss of cell adhesion to the ECM (Derksen *et al.*, 2006), and N-cadherin expression protects melanoma cells from anoikis (Li *et al.*, 2001).

Microtentacles

To extravasate from the circulation, cancer cells latch on to endothelial cells of the inner lining of blood vessels by forming specialized structures known as microtentacles. These structures, found in free-floating tumor cells and in CTCs *in vivo*, are known to enhance metastases. Unlike actin-based invadopodia, microtentacles are microtubule-rich protrusions that do not present ECM degradation activity. As dynamic, microtubule-enriched plasma membrane extensions, microtentacles are antagonized by the actin cytoskeleton as seen by the potentiation of microtentacles in cells treated with actin depolymerization drugs (Whipple *et al.*, 2007). Similarly, cofilin-mediated actin depolymerization promotes microtentacle formation by weakening the contraction of cortical actin (Vitolo *et al.*, 2013). Analogously, microtubule stabilization as well as stabilizing proteins such as tau, enhance microtentacles, facilitating tumor cell aggregation and attachment to the capillary endothelium of the microvasculature. Interestingly, Src kinase has been shown to differentially regulate microtentacles and invadopodia, suggesting that Src activity may act as a switch between the two protrusions (Balzer *et al.*, 2010). Examination of the molecular

constitution of microtentacles demonstrates that these protrusions are enriched in detyrosinated Glu-tubulin, a post-translationally modified form of α -tubulin that is found in stabilized microtubules.

Interestingly, the ectopic expression of the EMT-transcription factors Twist and Snail not only promotes α -tubulin detyrosination but also the formation of microtentacles in suspended cells (Whipple *et al.*, 2010). During EMT, tubulin tyrosine ligase enzyme is down-regulated, which leads to an increase in detyrosinated α -tubulin (Glu-tubulin), and, subsequently, an increase in microtentacles that penetrate the vascular endothelium to facilitate tumor cell reattachment during metastasis.

Conclusion

This article covers the major cellular programs utilized by metastatic tumor cells to invade and disseminate. Among them, we focused on the EMT program given its pleiotropic impact on cell migration and invasion. Although there is some debate as to how frequently EMT is used in human cancers, an abundance of work has demonstrated the critical role of the dynamic EMT in tumor invasion and metastasis. Upon EMT, carcinoma cells lose cell–cell junctions to allow single cell migration and acquire invadopodia to promote ECM degradation. Recently, it has been demonstrated that the plasticity of tumor cells also allows them to use different modes of migration, including collective cell migration, mesenchymal cell migration, and amoeboid migration in response to different extracellular stimuli and intrinsic alterations. Other cellular programs necessary for metastasis include anoikis resistance to allow survival under unfavorable ECM attachment and the formation of cellular structure microtentacles for attachment and extravasation from the blood vessels. Interestingly, many of the same factors that regulate EMT also control these cellular programs to promote successful invasion and dissemination. Further analysis of these cellular pathways will greatly improve our understanding of the process of metastasis and reveal novel targets for therapeutic intervention.

Glossary

Anterograde transport Movement of cargo along neurites away from the cell body.

Axon The cytoplasmic projection from the neuron that transmits information away from the cell body.

Axon transport The process of transporting proteins, ribonucleic proteins (RNPs), vesicles, and organelles to the axon from the cell body and from the axon back to the cell body.

Cytoskeleton Network of protein polymers and protein complexes (microtubules, neurofilaments, and actin) that provide structure to the cell.

Central nervous system Components of the nervous system that include the cerebrum, brain stem and cerebellum ('brain'), and spinal cord.

Dendrite Cytoplasmic projections from the neuron that transmit information toward the cell body.

Growth cone The most distal region of a growing axon. Growth cones contain receptors that respond to guidance

cues in the extracellular environment that help direct it to its appropriate final destination, as well as dynamic cytoskeleton to promote growth.

Local protein synthesis Synthesis of new proteins at peripheral sites in the cytoplasm. For neurons, this includes translation in axons and dendrites, utilize mRNAs, translation factors, and ribosomes that are actively transported to these sites.

Motor protein Protein complexes that use ATP to move cargo and transmit tractile forces within cells.

Peripheral nervous system Components of the nervous system that are 'peripheral' to brain and spinal cord. This includes peripheral nerves, spinal ganglia, autonomic ganglia, and enteric neurons.

Retrograde transport Movement of cargo from the neurites to the cell body.

Wallerian degeneration The active process of axon degradation to remove the segment that is no longer attached to the cell body after nerve injury.

Introduction

Neurons form the circuits that control and coordinate all animal behavior. These circuits are vital for normal function of the brain, spinal cord, and peripheral nerves. Intercellular communication generated by transfer of electrical activity between neurons and from neurons to target tissues is needed for every movement, sensation, and thought produced. A typical neuron is composed of three parts: a cell body, several dendrites, and an axon. The dendrites traverse short distances (≤ 2 mm) and bring activity to the cell body, while the axons are much longer and transmit activity away from the cell body. A neuron uses membrane depolarization to rapidly convey the information that is encoded by neural activity, from 'post-synaptic' sites in dendrites to the 'presynaptic' sites at the 'termini' of axons (i.e., intracellular communication). Arrival of such an 'action potential' at the axon terminus triggers release of neurotransmitters to propagate information across neural circuits or directly to the neuron's target (i.e., intercellular communication). The human neural circuits that connect motor cortex to spinal cord to muscle cover a distance approaching 2 m in some individuals. It is the axons of the motor cortex neuron and the spinal motor neuron that cover these long distances in the spinal cord and peripheral nerves, respectively. Disruption of axons through injury or disease blocks normal transmission of this neural activity and these long axonal processes are particularly vulnerable to damage.

While propagation of action potentials across these distances occurs on a millisecond time frame, neurons also use slower forms of intracellular communication by conveying

organelles, protein complexes, and RNA-protein complexes anterogradely and retrogradely in axons and dendrites. Axonal transport has been particularly well-studied, and has historically been separated into fast and slow components based on the speed of labeled proteins moving within axons. The fast component travels around 100 mm day^{-1} , while the slow component travels around 1 mm day^{-1} (Shah and Cleveland, 2002). The cargos that move in the fast component are important for the growing tips of developing axons ('growth cones') and for the proper function of mature synapses. These include organelles, membranes, proteins, and RNAs. Fast axonal transport also conveys signals to the cell body of the neuron that can regulate gene expression. The slow component of axonal transport ferries cytoskeletal polymers and other soluble proteins for maintenance of axon integrity (Shah and Cleveland, 2002). Movement of organelles and complexes within axons and dendrites is essential for neural function and plays key roles in neural repair.

'Molecular motors' or 'motor proteins' play the role of pack animals and messenger pigeons to move cargos to and from the neuron's cell body along axons and dendrites. There are several types of motors but all share certain attributes, being multisubunit protein complexes that harness the energy of ATP hydrolysis to move along 'cytoskeleton' tracks in axons and dendrites. The rates at which motors ferry cargo depends on a number of criteria, but *in vitro* speeds of individual mammalian motors and also membrane bound vesicles in axons have been clocked at up to $4 \mu\text{m s}^{-1}$. This speed is probably not maintained consistently, as transport cargos are frequently observed to pause and even reverse directions

within axons and dendrites. Nonetheless, the movement of cellular components over very long distances in relatively short amounts of time is a rather herculean task that requires a significant expenditure of energy. Regulation of motor protein motility, cargo composition, and the organization of the cytoskeleton tracks within neurons can dramatically influence neuronal function, particularly during the repair of neural connectivity after injury. Motor-dependent transport mechanisms are also prime targets for dysregulation in disease processes that affect the nervous system.

This article will cover the contributions of this subcellular trafficking to neural repair, focusing on the axon. During development, axon growth is characterized by a rapid elongation phase until targets are reached. At this point an alternate mode of arborizing growth allows axons to contact target cells and initiate synaptogenesis. This short-distance sprouting of axons may also underlie a presynaptic contribution to synaptic plasticity. It should be noted that development and regeneration of axonal processes share many common mediators; so much of this article will also be relevant to events in developmental growth. Furthermore, many of the mechanisms outlined here are also relevant for repair of dendritic processes; although we focus on the repair of axons because of their fundamental importance in long-range communication in the nervous system, the reader is referred to 'Further Reading' section for a recent publication examining mechanisms of dendrite repair.

Constituents for Intracellular Communication and Trafficking in Neurons

The Neuronal Cytoskeleton Provides Structure, Highways for Communication, and Growth Functions

The three components of the neuronal cytoskeleton, microfilaments, intermediate filaments, and microtubules, provide structural integrity for mature axons and dendrites. Their continued maintenance throughout the life of the animal supports normal axonal and dendritic function. During developmental and regenerative events the cytoskeleton itself is highly dynamic; polymerization and depolymerization of microtubules and microfilaments in the distal ends of axons (and dendrites) contributes to both growth and pathfinding for axons and dendrites (Lowery and Van Vactor, 2009). Posttranslational modifications to the cytoskeleton and associated proteins can contribute to neuronal cytoskeletal dynamics – for example, cyclin-dependent kinase 5 (CDK5) impacts all three components of the neuronal cytoskeleton (Smith, 2003). Motor proteins can contribute to cytoskeletal dynamics by moving short segments of cytoskeletal polymers or oligomers as cargo (Shah and Cleveland, 2002). This is particularly relevant during axon growth and arborization, but even after synapses are formed, transport of cytoskeletal components is likely to be important for maintenance of axons. The bulk of this movement appears to occur much more slowly than the speeds typically associated with fast axonal transport. However, this slow movement (and perhaps all of the slow component of axon transport) is thought to be driven by 'fast' motors that move the cargo intermittently (Li *et al.*, 2012).

Microfilaments

Microfilaments are composed of two strands of actin monomers twisted into helical filaments that have intrinsic polarity. All cells, including neurons, have a microfilament-rich, mesh-like network on the cytoplasmic side of the plasma membrane. This 'cortical actin' has been proposed to provide a tethering platform for non-translocating but active motors, allowing them to function in unison to move small microtubules and attached cellular components within axons and dendrites (Myers *et al.*, 2006). Polymerization and depolymerization of microfilaments at the distal end of growing axons and along the axon shaft, respectively, also play key roles in axon growth and branching. A large number of proteins have been identified that regulate actin dynamics and the spatial organization of actin filaments in growth cones (Lowery and Van Vactor, 2009).

Spectrin is another filamentous protein that is concentrated beneath the plasma membrane, providing a cross-link for the actin cytoskeleton and anchor for complexes of signaling and structural proteins, including membrane-linked protein complexes (Machnicka *et al.*, 2014). Different spectrin isoforms are concentrated in subdomains of the axon (e.g., axon initial segment, nodes of Ranvier) that are needed for neural function (Eshed-Eisenbach and Peles, 2013). Axonal spectrins can be rapidly proteolyzed following axonal injury (Buki *et al.*, 1999), so reconstruction of these axonal domains and repopulating the axon with spectrin is a key event in transitioning a regrown axon into a functional axon.

Intermediate filaments

Neuronal intermediate filaments do not provide tracks for motors, but these proteins have important roles in both axon function and growth. Neuron-specific intermediate filaments provide structural support for growing axons, and accumulation of one class of filaments, the neurofilaments, dictates the final caliber of an individual axon (Lee and Cleveland, 1996). The pathophysiology of some human diseases is accompanied by alterations in neurofilament deposition, including amyotrophic lateral sclerosis (ALS), Alzheimer's disease, Parkinson's disease, and several neuropathies (Perrot and Eyer, 2009). Posttranslational modification of the polypeptides that make up neurofilaments contributes to their axonal delivery (Szaro and Strong, 2010). The intermittent 'slow component' of microtubule-based transport of neurofilaments may contribute to the precise deposition of intermediate filaments along the axon (Shea and Lee, 2013). High levels of neurofilament mRNA and protein levels are typically associated with more mature neurons. In fact, synthesis of neurofilaments protein falls after axotomy of peripheral nerves and stays relatively lower during regeneration (Hoffman and Cleveland, 1988). In some cases phosphorylated neurofilaments accumulate in the soma of regenerating axons, suggesting that transport into growing axons is reduced (Goldstein *et al.*, 1987).

Another type of intermediate filament protein in neurons, peripherin, is expressed primarily in peripheral neurons. In contrast to neurofilament expression, peripherin expression increases during regenerative growth, falling back to basal levels as axons near their target tissues (Reid *et al.*, 2010). The axonal inclusions seen in some ALS model mice have been shown to include peripherin, and overexpression of the

ALS-linked protein TDP43 has been shown to cause a prolonged increase in peripherin expression after peripheral nerve injury (Swarup *et al.*, 2012). This implies that the ALS model has an altered course of neural repair.

Microtubules

Microtubules are the largest of the cytoskeletal polymers, and like microfilaments, have intrinsic polarity and the potential to be highly dynamic. Each microtubule is made of 13 parallel protofilaments, which are polymers of α - and β -tubulin heterodimers (Prokop, 2013). The organization of the heterodimers imparts the polarity to microtubules, with the α subunit nearer to the 'plus end' and the β subunit is nearer to the 'minus end.' In axons, microtubules have uniform polarity with distal plus ends oriented away from the cell body, but dendrites have mixed microtubule polarity (Baas and Lin, 2011). In motor-based transport this polarity is important because motor proteins typically prefer to move in either a

plus-end or minus-end direction (Figure 1(a)). Therefore, the polarity of microtubules creates a situation in which motors exhibit unidirectional movement in axons and bidirectional movement in dendrites.

Microtubules shrink and grow due to dimer addition and loss at their plus ends in a process called dynamic instability (Mitchison and Kirschner, 1984). Plus ends are the most dynamic, and have a cadre of associated proteins, known as 'plus end tracking proteins' (+TIPs), that regulate their behavior (Schuyler and Pellman, 2001). Growth and shrinkage occur less frequently at minus ends, in part because minus-end binding proteins can both protect against microtubule depolymerization as well as prevent addition of tubulin dimers (Goodwin and Vale, 2010). With neural injury, the microtubules and neurofilaments are depolymerized in the axon near the injury site on the proximal side (Figure 1(b)).

The importance of microtubules in axon growth has been known for decades. The expression of tubulins increases

during regeneration, recapitulating developmental expression levels (Hoffman and Cleveland, 1988). Microtubule polymerization is a critical and highly regulated process in axon growth; and drugs that inhibit polymerization can block axon growth in cultured neurons (Tanaka *et al.*, 1995). Interestingly, stabilization of microtubules with taxol can augment spinal cord regeneration (Hellal *et al.*, 2011). Microtubule acetylation has been linked to microtubule dynamics and to regeneration (see below) (Cho *et al.*, 2013). Microtubule-associated proteins (MAPs) also modify microtubule structure (e.g., ‘bundling’ of microtubules along the axon shaft), microtubule stability, and motor protein processivity (Hirokawa, 1994).

The Growth Cone Is Uniquely Suited for Its Job

The growing ends of developing and regenerating axons form a specialized structure called the ‘growth cone’ (Figure 1(c)). The shape and behavior of the growth cone is dictated by both extrinsic and intrinsic factors (Gomez and Letourneau, 2014). Examples of extrinsic factors are substrate molecules in the extracellular milieu or matrix (ECM) present along the growth trajectory, and molecules secreted locally into the environment by neighboring cells. Intrinsic factors include cytoskeletal dynamics that are often regulated by proteins within the growth cone like the Rho, Rac, and CD42 small GTPases, as well as the spatial distribution of receptors for sensing environmental cues. Generation of a growth cone after an axon is injured is generally thought to be essential for regenerative growth. One of the initial events in establishing a growth cone after injury is the entrance of calcium into the damaged axon – as outlined in subsequent sections, this triggers a number of changes that not only allow this important structure to form, but also facilitates signaling to the neuronal cell body (Bradke *et al.*, 2012).

While growth cones can vary greatly in shape and behavior, a typical advancing growth cone is composed of three major domains: central (C-), transition (T-), and peripheral (P-) domains (Gomez and Letourneau, 2014). The C-domain is made up of stable microtubule bundles that come from the axon shaft. These microtubules tend to be acetylated in the axon shaft and as microtubules enter the growth cone, tyrosination becomes the prominent posttranslational modification on the tubulins (Figure 1(c)). Acetylated tubulin is associated with stable polymers, while tyrosinated tubulin is associated with more dynamic polymers (Janke, 2014). The C-domain typically contains the more dynamic microtubules that can extend linearly in sync with the advancing edge of the growth cone. However, microtubules are responsive to environmental cues, and can shrink back or become curved in order to pause advancement or to reorient direction of growth (Lowery and Van Vactor, 2009). The P-domain at the very leading edge of the growth cone is composed of actin-based projections called lamellipodia and filopodia. Microfilaments in lamellipodia form a dynamic mesh, with new filaments being added to growing edge and old filaments being broken down at the back of the mesh near the C-domain. Force-generating myosin motors (see below) control the contractility of this meshwork (Medeiros *et al.*, 2006). The filopodia, are finger-like projections outward from lamellipodia that extend and retract to sample their environment. They contain

dynamic bundles of actin filaments, which are thought to form through the concerted action of myosin-driven ‘retrograde flow’ of the actin mesh in lamellipodia and the extension of actin polymers in the filopodia (Medeiros *et al.*, 2006).

The dynamic nature of the cytoskeleton in growth cones is what allows these structures to respond to environmental cues, and growth cones ultimately must transition into synaptic endings or other types of functional axon termini. When the growth cone adheres to a substrate such as laminin, the actin cytoskeleton becomes anchored to receptors, preventing retrograde movement of actin, which causes the filopodia of the growth cone to extend or protrude via distal actin polymerization (Mitchison and Kirschner, 1988). As this happens, myosin motors create tension between F-actin filaments and an F-actin arc at the base of the growth cone closest to the axon shaft. This allows microtubules of the C-domain to move forward, leading to an engorged growth cone; after this, the F-actin arc depolymerizes and the membrane collapses around the stable microtubule bundles, consolidating this region into an extension of the axon shaft (Lowery and Van Vactor, 2009). It should be noted that localized synthesis of β -actin protein and actin-interacting proteins in growth cones may also contribute to actin dynamics in the growth cone, as well as along the axon shaft where collateral branches form (Zhang *et al.*, 1999; Spillane *et al.*, 2013). Motor protein regulators (e.g., lissencephaly protein (Lis1) and nuclear distribution E-like 1 (Ndel1), see below) are prominent in growth cones of regenerating axons in culture (Smith *et al.*, 2000; Niethammer *et al.*, 2000), and can play an active role in promoting growth cone motility.

Molecular Motors Ferry Cargo to and from Axons and Provide Force Generation for Axon Growth

Molecular motors transport of a wide range of cargos in axons including organelles, vesicles, mRNA, and signaling molecules. The mRNAs move as RNA–protein complexes termed ‘ribonucleoproteins’ (RNPs) (Gomes *et al.*, 2014). Cargo may be deposited along axons, or trafficked anterogradely to synapses and growth cones or retrogradely back to the cell body. Transport along microtubules is carried out by kinesins, which for the most part are plus-end directed, and cytoplasmic dynein, which is minus end directed (Hirokawa *et al.*, 2010). Cytoplasmic dynein also has the capacity to become tethered to the cortical actin cytoskeleton within axons and growth cones. The force generating heads that project into the axon away from the cortical actin are then able to ‘kick’ short microtubule segments, causing them to move with their plus-ends leading (Mazel *et al.*, 2014). In addition to microtubule motors, axons contain myosin motors that ferry cargo on microfilament tracks. While these three classes of motors share common features, including motor domains that require ATP, they are also quite distinct with respect to molecular organization as well as motility regulatory mechanisms.

Kinesin

There are 14 classes of kinesin superfamily proteins organized in part by where the motor domain is located within the polypeptide (Hirokawa *et al.*, 2009). ‘Conventional’ kinesins in the Kinesin-1 group are heterotetramers. Two ‘heavy chains’

(kinesin heavy chain, KHC) form a dimer with globular head domains that interact with microtubules and undergo force-producing conformational changes in response to ATP binding and hydrolysis. KHC stalk regions contain the dimerization domains, while the C-terminal tails interact with 'light chains' (kinesin light chain, KLC) that confer cargo binding (Marx *et al.*, 2006). Though the motor domains are well conserved, substantial variability in other parts of the heteromer, including KLCs, can confer cargo selectivity. Kinesins move a variety of cargo toward axon termini, so they are critical for maintenance of mature axons and synapses, as well as for delivery of construction materials, receptors, adhesion proteins, and membranes to growing axons (Figures 1(a) and 1(b)). Different kinesins in this large superfamily are responsible for anterograde transport of specific cargo types within axons. Some of the specificity is likely derived from distinct heavy chains, but cargo-specific transport by the same heavy chain can be modulated by associated light chains (Hirokawa *et al.*, 2009).

Dynein

Although a few kinesins (e.g., KIFC2) may be capable of minus end-directed transport (Hirokawa *et al.*, 2009), the predominant minus end-directed motor in axons is cytoplasmic dynein (Figures 1(a) and 1(b)). This huge protein complex contains 12–14 subunits and has 2 identical heavy chains (dynein heavy chain, DHC) that form a dimer (Vale, 2003). The large ring-shaped motor domains at one end of DHC are ATPases, and are the force-generating component of the protein complex. A stalk extending from each DHC motor domain interacts with microtubules. DHC's stem interacts with an array of other 'chains.' These include two intermediate chains, 2–3 light intermediate chains and 3 distinct light chains. It is generally believed that the accessory subunits bind to adaptors that confer cargo specificity and/or control dynein processivity (Allan, 2011). The cytoplasmic dynein holoenzyme is fairly uniform in subunit composition. However, multiple genes encode related but distinct isoforms of each accessory subunit. Moreover, alternative splicing and post-translational modifications can alter subunit composition to optimize dynein motors for different tasks (Pfister *et al.*, 1996). Because axonal dynein moves retrogradely toward the cell body, it is important for molecular communication between axon endings and the nucleus. In intact axons, dynein carries information related to synapses and target tissues, and convey signals that prevent continued axon elongation after developmental growth has ceased (Smith and Skene, 1997).

Myosin

Myosin is a force-generating ATPase that underlies muscle contraction. The classic muscle myosin remains tethered in place and brings about muscle contraction by exerting tugging forces on actin filaments. Some myosins in neurons also function by exerting forces on the subcortical actin network (Figure 1(c)) – these are particularly prominent in regulation of growth cone dynamics needed for development and regeneration (Lowery and Van Vactor, 2009). Other members of the myosin superfamily are processive and can ferry cargo, using microfilaments as transport tracks. Some myosins (e.g., myosin Va) are plus-end directed, and others (e.g., myosin VI)

are minus-end directed (Kneussel and Wagner, 2013). Myosin transport is typically thought to occur over shorter distances than the long-range axonal transport associated with microtubule motors (i.e., at branch points, in growth cones, in synapses, etc.).

Regulation of motor proteins – Activation, inhibition, and cargo selectivity

Much of what we know about motor regulation has come from *in vitro* studies with purified proteins or cultured cells. However, studies in neuronal cultures suggest that these mechanisms are likely relevant to nerve repair. Because of their force-generating capacities, their plethora of cargos and the many cellular processes influenced by motors, a strictly enforced regulatory network must be in place to coordinate motor behaviors and modulate their behaviors in response to environmental cues and intrinsic cues. At the most basic level, ATP must be in good supply for all motors to function properly. Perhaps intuitively, mitochondrial ATP was shown to be the source of ATP for fast axon transport of mitochondria (Zala *et al.*, 2013). However, the source of ATP for transport of some vesicular cargos appears to be from glycolytic machinery directly associated with the vesicle (Zala *et al.*, 2013). Thus, the cargo itself can impact activity of the motor protein carrying it, and there is a growing understanding that complexes of motor proteins, scaffolds, and regulatory proteins can modulate motor processivity and force generation. The selection of a motor's cargo is in part regulated by cargo adaptors, proteins that bind to both the motors and to a specific type of cargo (Fu and Holzbaaur, 2014). An interesting new development is that mammalian cytoplasmic dynein is incapable of moving along microtubules *in vitro* in the absence of either cargo or cargo adaptor proteins (McKenney *et al.*, 2014; Schlager *et al.*, 2014). It remains to be determined if this is also the case within the confines of the axon shaft.

Knowledge of motor protein regulation has been advanced by studies of neurological disorders. For example, mutant forms of huntingtin (HTT) protein that cause Huntington's disease form aggregates in axons and dendrites that can block transport by motors (Lee *et al.*, 2004). Wild-type HTT can bind directly to dynein intermediate chain (DIC) subunits (Caviston *et al.*, 2007), while an HTT binding partner HTT-associated protein 1 (HAP1) interacts with KLC (McGuire *et al.*, 2006). Moreover, HTT is involved in linking the glycolytic machinery to cargo vesicles to provide a ready source of ATP for fast axonal transport (Zala *et al.*, 2013). While pathogenic HTT remains capable of interacting with motor complexes, it reduces motor association with microtubules through a c-Jun N-terminal kinase 3 (JNK3)-mediated phosphorylation of kinesin-1 (Morfini *et al.*, 2009).

Most organelles have all three classes of motors associated with them, usually more than one of each kind of motor. Interactions between motors may occur via scaffolding systems (Fu and Holzbaaur, 2014). There is growing evidence that motors of one class can affect activity of other classes of motors (Ally *et al.*, 2009; Levi *et al.*, 2006). While many of these interactions have been observed, how functions are coordinated to regulate cargo movement in the same axons has not been extensively studied. The precise trafficking of an individual cargo likely involves regulation of the stoichiometry

of motor association, a tug of war between opposing motors of all three classes, the proximity of transport tracks, as well as posttranslational modification of proteins and cargos (Fu and Holzbaur, 2014; Kardon and Vale, 2009). Each of these mechanisms is operant in the mature as well as injured and regenerating axon. One known molecular control mechanism involves the JNK-interacting protein 1 (JIP1) that acts as a scaffold protein that binds to both KHC and the dynein activator, dynactin (Fu and Holzbaur, 2013). JIP1 binding to KHC relieves an intramolecular autoinhibition of kinesin motor activity. The dynactin subunit p150^{Glued} competes with KHC for binding to JIP1 so that KHC is inactive when JIP1 is bound to p150^{Glued}. Kinesin dysinhibition and dynactin binding by JIP1 is regulated by JNK-dependent phosphorylation, which can lead to directional changes in movement of amyloid precursor protein-containing vesicles in axons (Fu and Holzbaur, 2013). JIP1 is also responsible for directional selectivity of autophagosomes in axons. Autophagosomes are retrogradely transported by dynein, and are presumed important for axonal maintenance and growth. Dual mechanisms appear to prevent activation of kinesin on these organelles (Fu et al., 2014). JIP associates with autophagosomes through the adaptor, microtubule-associated protein light chain 3 (LC3), and LC3 prevents JIP binding to KHC.

Other proteins can bind directly to motors and regulate force generation and/or processivity *in vitro* and also impact axon transport in cultured cells. For example, loss of Lis1 protein reduces retrograde transport of acidic vesicles and Lis1 overexpression increases speed and run lengths of retrogradely moving vesicles in axons (Pandey and Smith, 2011). Lis1 seems to function with dynein to promote microtubule advance during growth cone remodeling and fast axon growth (Grabham et al., 2007). During embryogenesis, Lis1 contributes to neuronal migration (Reiner and Sapiro, 2013), and it interacts with two paralogous dynein-binding proteins Ndel1 and Nde1 (Bradshaw et al., 2013). Ndel1/Nde1 also serves as a platform for modulation of motor activity by posttranslational modification. Ndel1/Nde1 strengthens the Lis1 association with dynein and increases force production by promoting cooperation between multiple dynein motors (McKenney et al., 2010). Interestingly, the neuronally enriched kinase Cdk5, phosphorylates Ndel1/Nde1 (Niethammer et al., 2000). Phosphorylation of Ndel1 by Cdk5 is important for dynein-dependent organelle transport in growing axons extended by adult sensory neurons in culture (Pandey and Smith, 2011). Recent evidence suggests that Cdk5 is an important regulator of membrane vesicle dynamics in growth cones (Tojima et al., 2014; Hsiao et al., 2014). Other kinases that contribute to regulation of axonal transport have also been observed to impact regeneration. For example, glycogen synthase kinase 3 (GSK-3) exerts a negative influence on axon transport in squid and fly axons (Morfini et al., 2002; Weaver et al., 2013). GSK-3 has shown varying effects on axon regeneration, but recent work indicates that sustained activation of GSK-3 supports regeneration of axons in peripheral nerve (Gobrecht et al., 2014). Clearly, the interplay between signals regulating axon transport and those regulating axon growth is complex, and just beginning to be understood.

How extracellular stimuli regulate motor proteins is also not well understood, but some pathways are beginning to

emerge. For example, activation of semaphorin receptors along growing axons stimulates both anterograde and retrograde movement of axonal vesicles (Li et al., 2004). Semaphorin stimulation of distal axons shifts α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptor subunit localization to dendrites through a coordinated retrograde signaling in axons and subsequent anterograde transport in dendrites (Yamashita et al., 2014). Neurotrophins also impact transport. These ligands increase endosome binding to dynein through DIC phosphorylation, thereby stimulating retrograde transport (Mitchell et al., 2012). Interestingly, neurotrophin receptors (Trks) are endocytosed in axons along with their ligands and can be retrogradely transported as a 'signaling endosome' that carries downstream effector kinases to the cell body (Schmieg et al., 2014). During development, many neuronal populations compete for binding to target-derived neurotrophins and other trophic agents. The neurons that do not secure an appropriate source of trophic support are eliminated through naturally occurring cell death. Culture preparations in which the neurons' cell body and axons are compartmentalized have shown qualitative differences in the response to neurotrophic stimulation of distal axons compared to the cell body (Campenot and MacInnis, 2004). This suggests that the signaling endosome conveys a signal different from Trk receptors endocytosed along the cell body.

Activation of Trk receptors along the axon has been shown to modulate transport of RNPs into axons, with accumulation and translation of mRNAs adjacent to the trophic stimulus along axons (Willis et al., 2007). Target-derived nerve growth factor (NGF) in sympathetic neurons was recently shown to coordinate transcriptional responses in the cell body with delivery of mRNA encoding a survival promoting protein, B-cell lymphoma w (Bcl_w), to the axons (Cosker et al., 2013). Given that peripheral nervous system (PNS) injury results in increased expression of neurotrophins and other trophic factors by Schwann cells in the severed nerve stump (Funakoshi et al., 1993), it is intriguing to hypothesize that signaling endosomes moving retrogradely to the cell body would be used to coordinate anterograde delivery of macromolecules to the regenerating axons. The cargos that motor proteins deliver into axons obviously play a role growth and regeneration. The axon needs new cytoskeleton and membrane components to grow, as the severed segment of the axon distal to injury site undergoes Wallerian degeneration in mammals (see below). It was also recently recognized that protein products of axonally transported mRNAs support regeneration in the PNS (Donnelly et al., 2013), and there is some evidence that this may occur after spinal cord injury as well (Willis et al., 2011).

Neural Repair Mechanisms

Injury Changes Axon Structure and Axonal Transport to Initiate a Regeneration Program

With damage and severing of an axon, the segment distal to the site of injury (i.e., the portion no longer connected to the cell body) is actively degraded through Wallerian degeneration. In the portion proximal to the site of injury, influx of Ca²⁺ from extracellular spaces promotes membrane sealing and locally activates proteases (Bradke et al., 2012). Proteases

degrade axonal proteins including cytoskeletal elements, and this is necessary for the initiation of axonal growth (Ziv and Spira, 1997). The increase in axoplasmic Ca^{2+} also triggers retrograde signaling through transport mechanisms (Rishal and Fainzilber, 2010). This shift in retrograde transport ultimately helps to turn on expression of genes that support growth (regeneration-associated genes (RAGs)) and turn off expression of genes associated more with mature neuronal functions (Rishal and Fainzilber, 2010). For example, axotomy in the PNS increases the expression of growth-associated protein-43 (GAP-43) and $\text{T}\alpha 1$ -tubulin, but decreases expression of neurofilaments. Injury to the mammalian brain or spinal cord, in contrast to peripheral nerves, often does not activate expression of RAGs, and this may in part, underlie the reduced growth capacity of mammalian central nervous system (CNS) neurons after injury (Hoffman, 2010). Many strategies to increase axon regeneration after central injuries have focused on altering the 'intrinsic growth capacity' of CNS neurons through changing gene expression programs (Mar *et al.*, 2014). ECM glycoproteins and glial-derived proteins in the injured brain and spinal cord also actively block axon growth, and overcoming these 'roadblocks' is often a complimentary strategy to support CNS neural repair (Geoffroy and Zheng, 2014).

Some of the mechanisms that underlie the shift in retrograde axonal transport are known. Axonal JNK3 is locally activated after injury, with a resulting increased association of a complex of JNK-interacting proteins 3 (JIP3) and activated JNK3 with the p150^{Glued} subunit of dynactin, and increased retrograde transport of activated JNK3 (Cavalli *et al.*, 2005). This leads to activation of c-Jun in the neuronal cell body that presumably supports expression of genes needed for regeneration (Ruff *et al.*, 2012). Interestingly, JIP3 binding to KHC can also increase kinesin motility (Sun *et al.*, 2011). It is not clear whether the JIP1-dependent retrograde transport of autophagosomes mentioned above contributes to neural repair; however, it is intriguing that both JIP1 and JIP3 can coordinate anterograde and retrograde transport (Fu and Holzbaur, 2014). This provides a powerful mechanism to coordinate transport to meet physiological needs of the neuron and potentially to recycle proteins between axons and cell body.

Calcium influx coordinates the injury response

The influx of Ca^{2+} into injured axons also triggers translation of locally stored mRNAs (Perry and Fainzilber, 2014). These mRNAs are transported into axons as RNPs and it remains unclear exactly how Ca^{2+} influx activates translation locally in axons, but it likely includes a commensurate release of Ca^{2+} stores from sites in axons (Vuppalaanchi *et al.*, 2012). Axonal mRNAs known to be translated by increased axoplasmic (Ca^{2+}) include Importin $\beta 1$, Ran specific binding protein 1 (RanBP1), and vimentin (Gomes *et al.*, 2014). These encode proteins that contribute to a retrograde injury signal in a complex highly orchestrated process (Rishal and Fainzilber, 2010). The newly translated Importin $\beta 1$ in axons heterodimerizes with Importin $\alpha 3$ (Hanz *et al.*, 2003). Localized synthesis of RanBP1 facilitates this by releasing $\alpha 3$ from an anterograde transport complex (Yudin *et al.*, 2008). Interaction of the Importin $\beta 1/\alpha 3$ complex with dynein is needed for the transport of proteins containing nuclear localization signal (NLS) to the nucleus. The cargo of the dynein-Importin $\beta 1/\alpha 3$

complex includes other proteins that are locally synthesized with injury (e.g., signal transducer and activator of transcription 3 α , Stat3 α) as well as proteins that are locally activated through injury-induced posttranslational modifications (e.g., extracellular-regulated kinase, Erk 1/2) (Ben-Yaakov *et al.*, 2012; Perlson *et al.*, 2005). Vimentin has been considered as a glial intermediate filament protein in the nervous system, but vimentin can be expressed in neurons, and its mRNA has been shown to localize to axons (Willis *et al.*, 2007). Curiously, proteolytic cleavage of vimentin in injured axons generates a 'scaffold peptide' for activated Erk 1/2, a mitogen-activated protein kinase (MAPK), to bind to Importin $\beta 1/\alpha 3$ dimer. This kinase is transported to the cell body with dynein, where it activates Elk1 (and possibly other) transcription factors (Perlson *et al.*, 2005). It is likely that such a posttranscriptional mechanism is shared with other physiological responses of axons, since neurodegenerative stimuli, neuronal survival promoting stimuli, and a neurotropic virus are now recognized to couple events in the distal axons to cell body responses through translation of axonal mRNAs (Koyuncu *et al.*, 2013; Baleriola *et al.*, 2014; Cox *et al.*, 2008; Cosker *et al.*, 2013). These and other studies indicate that axonal injury induces a localized, integrated response to shift retrograde transport toward cargos that assist in mounting a regenerative response. The full extent of these cargos has yet to be determined; the reader is referred to references in 'Further Reading' section below for additional information on cargos.

Calcium influx transforms the injured axon to support regenerative growth

Much of what we know about axonal transport and localized growth mechanisms have been derived from studies in cultured neurons, where events can be spatially and temporally monitored with high precision. Neurons cultured from invertebrate organisms have provided a platform for visualizing cytoskeletal dynamics in growing and injured axons. For example, the initial studies on Ca^{2+} signaling after axonal injury resulted from work in *Aplysia* neurons (Ambron and Walters, 1996). The Ca^{2+} gradient that forms in these axons after injury occurs in both the proximal (intact) and distal (severed) segments of the injured axon, but only the proximal end undergoes regeneration (Ziv and Spira, 1997). The Ca^{2+} dependent events including membrane sealing and cytoskeletal restructuring controlled by calcium-activated calpain, syntaxin, synaptotagmin, and synaptobrevin are critical for neural repair (Bradke *et al.*, 2012). Indeed, activation of calpain through a Ca^{2+} -dependent mechanism is required for growth cone formation (Gitler and Spira, 2002). Proteolysis of cytoskeletal elements in the cut axon results in a reorganization of microtubule polarity in *Aplysia* (Sahly *et al.*, 2006). This may generate a 'trap' for capturing both anterogradely and retrogradely transported vesicles, which are then available to fuse with the plasma membrane for efficient and effective formation of a growth cone (Erez and Spira, 2008). Work in vertebrate neurons indicates that activation of localized protein synthesis in the distal cut axon is also needed for growth cone formation (Verma *et al.*, 2005). Though the proteins synthesized were not identified, TC10 and Exoc3 mRNAs, which encode components needed for plasma membrane expansion, are locally translated in growing axons (Gracias *et al.*, 2014). Stimulation of MAPKs and

mammalian target of rapamycin (mTOR) converge on protein synthesis machinery and are needed for growth cone formation (Bradke *et al.*, 2012). Thus, localized mRNA translation supports the initial transition of an injured axon into a regenerating axon. Subsequent growth of the axon requires delivery of necessary building blocks of cytoskeleton and membrane components, which is accomplished by anterograde transport of proteins, vesicles, and RNPs.

Unexpected Roles for Proteins in Growing Axons

Axonal functions for nuclear proteins

With technical advancements in subcellular imaging, protein/RNA detection and analyses, and study of signal transduction mechanisms, previously unrecognized functions have been ascribed to proteins and protein networks that support neural repair. For example, epigenetic regulation is now well recognized as a means to modulate expression of entire gene families, and there is clear potential for such chromatin-based modulation to contribute to neural repair (Finelli *et al.*, 2013). However, recent work from two groups have uncovered intra-axonal functions for histone deacetylase (HDAC) proteins that are classically viewed as modifiers of chromatin structure and, hence, transcription. The injury-induced Ca^{2+} entry into axons noted above produces a retrograde ' Ca^{2+} wave' that triggers exit of HDAC5 from the nucleus in a protein kinase C-dependent pathway. In keeping with classic functions of HDACs, the loss of HDAC5 from the nucleus supports expression of genes whose encoded proteins have roles in regeneration (e.g., c-Fos, c-Jun, KLF4, KLF5, and Gadd 45a; see Cho *et al.*, 2013 and references within). However, HDAC5 is also anterogradely transported into the injured axon, where it supports deacetylation of microtubules. This decreases stability of microtubules in the cut axon that is needed for growth cone formation just proximal to the injury site. Curiously, this anterograde movement of HDAC5 only occurred after peripheral nerve injury and not after optic nerve injury, a lesion of CNS axons (Cho *et al.*, 2013), pointing to another distinction between the central and PNS with axonal injury (Cho *et al.*, 2013). HDAC6 protein has also been shown to function in axons, but inhibition of HDAC6, rather than activation, brings growth-promoting effects (Rivieccio *et al.*, 2009). For HDAC6 inhibition, this allows for growth on nonpermissive substrates including myelin-associated glycoprotein and CSPGs that block axonal growth after spinal cord injury. These observations suggest that HDAC5 and HDAC6 have antagonistic functions in neural repair. However, HDAC6 may contribute to axon health because it facilitates the retrograde transport of protein aggregates for destruction in autophagosomes (Lee *et al.*, 2010). It will be intriguing in the coming years to discover the mechanism of action and targets of these deacetylases in developing, regenerating the mature axons.

New functions for adenomatous polyposis coli protein, a protein associated with colorectal cancer

Other proteins have shown multifunctionality that impacts axon development and likely axon regeneration. Adenomatous polyposis coli protein (APC) is a large, multidomain microtubule-interacting protein initially discovered because

truncating mutations lead to colorectal cancer in humans (Vogelstein and Kinzler, 2004). APC has also been linked to axon growth through promoting microtubule polymerization (Chen *et al.*, 2011). In addition to its function as a +TIP, APC interacts with many different proteins including β -catenin and GSK-3 β from the canonical Wnt signaling pathway (Clevers and Nusse, 2012). Initial studies in fibroblasts raised the possibility that APC's actions may also extend to interaction with mRNAs (Mili *et al.*, 2008). More recent work has shown that APC binds directly to more than 250 neuronal mRNAs (Preitner *et al.*, 2014). Interestingly, nearly half of those mRNAs were known to localize into growing axons of PNS sensory neurons, including the Importin β 1 and β -actin mRNAs that are mentioned above. Preventing APC binding to a tubulin isoform mRNA (TUBB2B2) decreased axonal levels of this mRNA and caused growth cones to shrink, which could significantly hamper the growth cone's ability to interact with growth substrates (Preitner *et al.*, 2014). Though it is not clear whether APC is needed for transport or translation of these mRNAs (or both), the protein is perfectly positioned in the growth cone to serve as a scaffold concentrating mRNAs and translational machinery near the processive tips of microtubules. There is work in developing neurons indicating that localized mRNAs accumulate along with translation factors and ribosome subunits adjacent to cytoplasmic tails of axon guidance receptors (Tcherkezian *et al.*, 2010). It will be interesting to see if APC also contributes to transport or translation of mRNAs in injured axons where localized protein synthesis is known to contribute to regeneration.

A protein kinase that can regulate both axon regeneration and Wallerian degeneration

Genetic screens in model organisms, including flies, worms, and mice, identified the 'dual leucine zipper kinase' (DLK) as regulator of both axon regeneration and degeneration (Tedeschi and Bradke, 2013). DLK has also been called 'ZPK' in mice and 'Wallenda' in *Drosophila*. Loss of DLK delays degeneration of axons but also attenuates RAG transcription in the cell body (Shin *et al.*, 2012a). Activation of DLK can lead to downstream activation of both JNK and 38 kDa mitogen-activated protein kinase (p38^{MAPK}). As emphasized above, JNK activation is important in neural repair, and downstream c-Jun dependent transcription activates expression of RAGs in the cell body after axonal injury (Shin *et al.*, 2012a). However, blocking JNK activation in severed axons distal to the injury site delays Wallerian degeneration, indicating dual functions for both DLK and JNK (Ferraris *et al.*, 2013). In addition to JNK's roles in axonal transport mediated through JIPs, JNK is known to target microtubule binding proteins that regulate dynamic stability of these cytoskeletal elements, which can influence both axon formation and regeneration (Tedeschi and Bradke, 2013). JNK phosphorylation triggers degradation of super cervical ganglion clone 10 (SCG10, also called Stathmin-2) in axons (Shin *et al.*, 2012b). SCG10 is a membrane bound protein that destabilizes microtubules (Riederer *et al.*, 1997). Degradation of SCG10 in the severed axon is linked to Wallerian degeneration, but SCG10 is rapidly replenished in the proximal axon segment proximal to the injury and this is needed for regeneration (Shin *et al.*, 2014). Destabilization of axonal microtubules through SCG10's actions near the growth

cone contributes to axon motility. JNK is also known to phosphorylate microtubule-associated protein 1b (MAP1b) in axons, which conversely increases stability of microtubules (Chang *et al.*, 2003). Interestingly, the mRNA encoding a protein kinase that can be an intermediate between DLK and JNK, MKK7, or mitogen-activated protein kinase kinase 7 (MAP2K7), localizes to proximal neurites of differentiating NIE-115 cells and primary hippocampal neurons (Feltrin *et al.*, 2012). This may provide a means to compartmentalize the functional outcome of JNK's activation in growing axons, by concentrating substrates that differentially modify microtubule dynamics to different sites along the axon (e.g., growth cone for destabilization vs. axon shaft for stabilization).

Regulation of microtubule motor proteins can directly support axon regeneration

Interestingly, kinesin and dynein motors have recently been shown to have unexpected roles in attenuating axon growth. The levels and/or activity of kinesin and dynein motors may contribute to axonal growth by providing a gauge for how much material the axon needs in order to grow (Albus *et al.*, 2013). In cultures of adult sensory neurons, partial depletion of kinesin and/or dynein heavy chains with siRNA actually increases axon length over time (Rishal, 2012). Legs at odd angles (Loa) mice that have reduced levels of dynein heavy chain 1 (Dync1h1) show increased axon length in developing limb buds indicating that this length sensing mechanism is also relevant for axon growth *in vivo* (Rishal, 2012). These data suggest that continual anterograde and retrograde signaling, analogous to a radar signal, contributes to axon growth rates (Kam *et al.*, 2009). However, the cargos that are needed for this, both those carried anterograde into the axons and those carried retrograde back to the cell body, are not clear.

Work from the Baas group using depletion of kinesins also suggested that localized interactions of kinesin and dynein motors could affect axon length (Liu *et al.*, 2010). They observed that partial depletion of kinesin-5 or kinesin-12 increased axon length in cultured neurons, but attributed this to a shift in the tractile forces along the distal axon to favor increased growth (Myers and Baas, 2007; Liu *et al.*, 2010). They hypothesized that loss of either kinesin allows cytoplasmic dynein to pull microtubules in the opposite direction, moving more microtubules from the axon shaft into the growth cone, resulting in both increases in axon length and the inability of the growth cone to turn properly without spatial control over the microtubules in the growth cone (Liu *et al.*, 2010). Regardless of whether this is a cargo-dependent signaling mechanism or localized force differentials through altered motor stoichiometry, the end result of decreasing motor protein activity results in the counter-intuitive effect of increasing axon length. It will be of substantial interest to determine how these mechanisms can be integrated with the injury-dependent and regeneration-associated changes in axonal trafficking outlined above that are essential for repair of neural connectivity.

Perspectives

Despite all that has been learned of neural repair mechanisms and the potential for using trafficking to encourage axons to

regrow after injury, even in the PNS where regeneration is relatively robust, regenerating axons only progress at 1–2 mm per day. Thus, finding a means to increase growth rates should bring huge benefits. However, whether increased growth rate can be accomplished by modulating axon transport dynamics *in vivo* remains to be determined. Interesting potential targets for regulating axon growth through trafficking include the motors themselves, their regulatory partners, kinases, cargo adaptors, and specific cargos.

In addition to overt axon elongation driven by growth cone advance, developing neurons must also undergo a different kind of axon growth even after synapse formation. Small-scale axon growth and remodeling of synaptic connections occur throughout adult life and underlies learning and memory. But this does not compare to increased length that nerves and axon tracts accomplish during growth from a late stage embryo to late adolescent, and is unlikely to be the mechanism underlying this elongation. There is some evidence that neurons switch to a stretch-induced interstitial growth as organisms increase their rostral-to-caudal dimensions (Suter and Miller, 2011). Cultured sensory neurons have been 'stretched' in an attempt to model this process, and within limits, stretching results in increased rates of axon growth while maintaining electrophysiological function (Pfister *et al.*, 2006). The mechanisms underlying this increased growth are not clear, but it would seem that the axon must lay down more cytoskeleton and membrane or suffer compromised integrity. Adult neurons also seem to tolerate this axon stretching less well than embryonic neurons, which could relate to age acquired cytoskeletal modifications or loss of developmental gene expression programs (Loverde *et al.*, 2011). Still the concept of stretch-induced growth may be a promising lead for future neural repair strategies once the mechanism(s) can be uncovered, particularly if this might complement other growth-promoting strategies.

There are intersections between neural repair, axonal transport, and neurodegenerative mechanisms that warrant mention. As indicated above, DLK and SCG10 have dual roles in regeneration and axonal degeneration. The severed axon has lost its cell body source of proteins, RNPs, and organelles. Consequently, this severed axon segment needs to survive on existing entities, or gather what it needs from its local environment (e.g., glia). To some extent, defects in axonal transport can result in a similar situation. Reduced anterograde delivery of axonal components produced in the cell body and reduced transport of signals originating in distal targets can compromise the health of the neuron. Indeed, transport defects can be a key factor in neurological diseases and mutations or depletion of motor proteins or their regulators are emerging as causative agents in disease. Beyond Huntington's disease mentioned above, defects in axon transport in age-related dementias such as Alzheimer's disease (Kanaan *et al.*, 2013). The distances that motor axons traverse may make them particularly vulnerable to transport deficits. Consistent with this notion, a KHC mutation that disrupts microtubule binding has been found in patients with hereditary spastic paraplegias, mutations in mouse DHC lead to an ALS-like motor neuron degeneration (Fichera *et al.*, 2004; Ikenaka *et al.*, 2012) and a mutation in the p150^{Glued} dynactin subunit has been found in an autosomal dominant form of lower motor neuron disease (Puls *et al.*, 2003).

Symptoms of neurodegenerative diseases including ALS have been linked to loss of synapses that may be initiated by 'dying back' of the distal axon (Adalbert and Coleman, 2012). Blocking the degeneration of their axons can prevent the death of neurons in some neurodegenerative diseases. For example, deletion or inhibition of DLK is neuroprotective in cellular and animal models of Alzheimer's disease, Parkinson's disease and glaucoma (Ferraris *et al.*, 2013). Expression of axonally targeted Ube4b-NMNAT1 fusion protein (Wallerian degeneration slow protein, 'Wld^s') can delay Wallerian degeneration and prevent neuron loss in several different animal models of neurodegeneration (Coleman and Freeman, 2010). Delayed degeneration occurs because the Wld^s protein maintains nicotinamide adenine dinucleotide (NAD⁺) levels in the severed axons. Normally axons contain NMNAT2 that fulfills the same enzymatic function to maintain NAD⁺, but NMNAT2 has short a half-life and must be continually replenished by anterograde transport (Gilley and Coleman, 2010). If transport becomes compromised, the neuron can be placed in the vulnerable position of losing its axon. Intriguingly, work in ALS animal models pointed to a shift in the retrogradely transported cargos from 'pro-survival' cargos to 'stress-related' cargos with increasing severity of neurodegeneration (Perlson *et al.*, 2009). The similar responses in physical injury of the axon and neurodegenerative diseases suggest the possibility that neurons in both cases may be mounting, or attempting to mount, a regenerative response, although few studies have addressed this possibility. Coordination of several signal transduction pathways and intracellular trafficking/signaling is needed to mount and maintain a regenerative response. Small alterations in these pathways could effectively alter function, growth, and maintenance of the axon.

Introduction

mTOR belongs to the phosphoinositide-3-kinase (PI3K)-related family of protein kinases (Lempiäinen and Halazonetis, 2009) and primarily functions to promote cell growth and metabolism (Wullschlegel *et al.*, 2006; Laplante and Sabatini, 2012). At least two distinct multi-protein complexes, termed mTOR complex 1 (mTORC1) and mTOR complex 2 (mTORC2) (Hara *et al.*, 2002; Kim *et al.*, 2002; Loewith *et al.*, 2002; Jacinto *et al.*, 2004; Sarbassov *et al.*, 2004), are defined by their unique cofactors (Figure 1), including Raptor and PRAS40 for mTORC1 and Rictor, Sin1, and Protor for mTORC2 (Jacinto *et al.*, 2006; Yang *et al.*, 2006; Sancak *et al.*, 2007; Vander Haar *et al.*, 2007; Pearce *et al.*, 2007), while core factors common to both complexes include mLST8 (GbetaL) and Deptor (Kim *et al.*, 2003; Peterson *et al.*, 2009). It is noteworthy that novel mTORC1 and mTORC2 components and their substrates continue to emerge, expanding our knowledge of each mTOR complex.

mTORC1 and mTORC2

Raptor and PRAS40 are mTORC1 Subunits

Raptor, an essential component of mTORC1, functions as a scaffold for mTOR kinase to recruit and phosphorylate specific substrates such as ribosomal protein S6 kinases (S6Ks) and the eukaryotic translation initiation factor 4E binding proteins (e4EBPs). This specific substrate recruitment by mTORC1 occurs through a direct interaction between Raptor and the TOR signaling (TOS) motif, a conserved five amino acid sequence often found in these substrates (Nojima *et al.*, 2003; Schalm and Blenis, 2002; Schalm *et al.*, 2003). Importantly, recent studies have revealed another important function of Raptor in

guiding the subcellular localization of mTORC1. In response to amino acid availability, Raptor associates with Rag small GTPases that localize to the surface of lysosomes. This action is important for the recruitment of mTORC1 to the lysosome membrane for its activation (see Section Regulation of mTOR Signaling by Amino Acids for the details) (Sancak *et al.*, 2008, 2010). Thus, Raptor serves to link not only mTOR kinase with its substrates, but also mTOR to the lysosome membrane for its activation. In contrast to its positive roles in the regulation of mTORC1 signaling, Raptor also interacts with PRAS40, a specific negative regulator for mTORC1 (Sancak *et al.*, 2007; Vander Haar *et al.*, 2007). It has been suggested that the interaction of PRAS40 with Raptor through a TOS-like motif suppresses mTORC1 phosphorylation of other substrates by directly competing for mTORC1 (Wang *et al.*, 2007; Oshiro *et al.*, 2007). Importantly, active Akt kinase stimulates mTORC1-dependent S6K1 and 4EBP1 phosphorylation by directly phosphorylating Thr246 of PRAS40, which induces the dissociation of PRAS40 from mTORC1 and mitigates the inhibitory effect of PRAS40 on mTORC1-dependent phosphorylation of its substrates (Sancak *et al.*, 2007; Vander Haar *et al.*, 2007).

mLST8 and Deptor are Common Components of mTORC1 and mTORC2

mLST8 is a common component of both mTORC1 and mTORC2. Knockdown of mLST8 expression in HEK293T cells using siRNAs decreases S6K1 phosphorylation (Kim *et al.*, 2003) suggesting mLST8 to be required for mTORC1 activity. However, a subsequent study in *mLST8*^{-/-} mouse embryonic fibroblasts (MEFs) indicated that mLST8 loss-of-function does not affect mTORC1 activity, mTORC1 integrity, or the

Figure 1 The mTOR signaling pathway. The key signaling nodes that regulate mTORC1 and mTORC2 and the representative outputs of the mTORC1 and mTORC2 pathways.

interaction between mTORC1 and its substrates (Guertin *et al.*, 2006). Instead, the activity of mTORC2 was completely abolished in *mLST8*^{-/-} MEFs, suggesting an essential role for mLST8 in mTORC2 function. Thus, the functional importance of mTORC1 in the regulation of mTORC2 remains to be fully resolved.

Deptor is another common component of mTORC1 and mTORC2. Initial findings indicated Deptor exerts inhibitory effects on both mTORC1 and mTORC2 (Peterson *et al.*, 2009). In a subset of multiple myeloma cells, enhanced Deptor expression leads to strong inhibition of mTORC1, which relieves mTORC1-dependent inhibition of the PI3K pathway, and results in the activation of Akt and cancer cell survival (Peterson *et al.*, 2009). However, recent studies demonstrate that phosphorylation of both Akt and S6K1 are enhanced in BAF60c transgenic mice, where Deptor is highly expressed (Meng *et al.*, 2013). Moreover, Deptor does not significantly affect mTORC1 activity in adipocytes as neither overexpression nor knockdown of DEPTOR affected phosphorylation of S6K1 (Laplante *et al.*, 2012). Taken together, these observations suggest the differential effects of Deptor on mTORC1 activity are likely to be cell or tissue type specific. Therefore, the elucidation of the molecular mechanisms underlying Deptor-dependent mTORC1 regulation requires further investigation. Intriguingly, recent studies have shown that the stability of Deptor expression is negatively regulated by mTORC1. Deptor is phosphorylated by mTORC1 (mTOR) and/or S6K, resulting in enhanced proteasome-mediated degradation of Deptor. These new observations suggest that mTORC1 exerts a positive feedback loop on its own activity by releasing the inhibitory effects of Deptor (Gao *et al.*, 2011; Zhao *et al.*, 2011).

A Brief Introduction to mTORC2

mTORC2 regulates cell survival, metabolism and cytoskeleton organization through the phosphorylation of AGC kinase family members, such as Akt, PKC, and SGK1 (Sarbasov *et al.*, 2006; Jacinto *et al.*, 2004; Ikenoue *et al.*, 2008). Relative to mTORC1, the properties of mTORC2 are less well characterized, likely due to the lack of specific mTORC2 inhibitors. mTORC2 responds to growth factors, but not to nutrients or cellular energy. The mechanism by which growth factors activate mTORC2 is not fully characterized. A recent study demonstrated that, in response to growth factors, the association of mTORC2 with ribosomes appears to be a key event for the activation of mTORC2 (Zinzalla *et al.*, 2011). Rictor is an essential and characteristic component of mTORC2. Sin1 and mLST8 are also essential for mTORC2 function, as depletion of either abolishes mTORC2 activity (Yang *et al.*, 2006; Jacinto *et al.*, 2006; Guertin *et al.*, 2006).

The Effect of Rapamycin on mTORC1 and mTORC2

mTORC1 activity is sensitive to rapamycin, a macrolide originally developed as an antifungal agent. Rapamycin strongly interacts with FK506-binding protein 12 (FKBP12), and this drug-protein complex binds to the FKBP12-rapamycin-binding (FRB) domain of mTOR kinase (Choi *et al.*, 1996). The FRB domain acts as a gatekeeper as its rapamycin binding site interacts with substrates to grant them access to the restricted active site of mTOR kinase. The rapamycin-FKBP12 therefore allosterically inhibits mTOR kinase by blocking substrate

recruitment and further restricts the accessibility of substrates to the active site of mTOR kinase (Yang *et al.*, 2013).

Unlike the effect of ATP-competitive mTOR kinase inhibitors, which completely inhibit mTORC1-dependent phosphorylation of its substrates, effects of rapamycin on the phosphorylation of mTORC1 substrates vary (Thoreen *et al.*, 2009; Feldman *et al.*, 2009). For example, the mTORC1 site on S6K1 is highly sensitive to rapamycin while sites on 4EBP1 are less sensitive. Interestingly, the dimerization of mTORC1 is required for 4EBP1 phosphorylation but not for S6K1 phosphorylation (Yip *et al.*, 2010). In addition, prolonged rapamycin treatment weakens the interaction between mTORC1 and Raptor, and disrupts the dimer formation of mTORC1. This study suggests that the contact of the rapamycin-FKBP12 complex with the FRB domain of mTORC1 may be sufficient to block access to the active site for larger sized substrates such as S6K1. In contrast, disruption of the mTORC1 dimer is required to block mTORC1-dependent phosphorylation of 4EBP1.

Although the rapamycin-FKBP12 complex directly binds and limits the accessibility of substrates to the active kinase site, it has little effect on mTOR kinase activity of mTORC2. However, prolonged rapamycin treatment inhibits mTORC2 from phosphorylating its substrates in some cell types by attenuating the formation of the mTORC2 complex (Sarbassov *et al.*, 2006). These observations suggest that specific components of mTORC2 may prevent rapamycin-FKBP12 from gaining access to the FRB domain of mTOR kinase. However, prolonged rapamycin treatment may allow the rapamycin-FKBP12 complex to access newly synthesized mTOR kinase and prevents the formation of mTORC2.

Downstream of mTORC1

Consistent with the functional roles of mTORC1 in promoting cell growth and proliferation, the effectors characterized as downstream targets of mTORC1 are largely comprised of factors that regulate protein synthesis, cell metabolism, cellular organelle synthesis, and protein degradation (Wullschlegel *et al.*, 2006; Figure 1). At the cellular level, mTORC1 functions as a critical regulator of translation initiation, the rate-limiting step of protein synthesis in which ribosomes are recruited to mRNAs (Mamane *et al.*, 2006).

S6K1 and 4EBP1 Are the Best-Characterized mTORC1 Substrates

S6K1 and 4EBP1 represent the first TOR substrates identified in metazoans and remain the best characterized. S6K1 regulates translation initiation, mRNA processing, metabolism, and cell size. Genetic evidence indicates that the ablation of dS6K in *Drosophila* reduces cell and body size (Montagne *et al.*, 1999). Mice lacking functional S6K1 also show a small body phenotype, resistance to high fat diet-induced obesity, and improved insulin sensitivity (Um *et al.*, 2004). At the molecular level, mTORC1 phosphorylates S6K1 on Thr389 and Ser371 (Burnett *et al.*, 1998; Weng *et al.*, 1998; Moser *et al.*, 1997). mTORC1 phosphorylation on Thr389 generates the binding motif on S6K1 for 3-phosphoinositide dependent

protein kinase 1 (PDK1), which further phosphorylates S6K1 on Thr229 that lies in the S6K1 activation loop (Alessi *et al.*, 1998; Pullen *et al.*, 1998). These sequential phosphorylations lead to the full activation of S6K1, thereby initiating the downstream cellular events. S6K1 interacts with a component of the eukaryotic translation initiation factor 3 (eIF3) complex when mTORC1 activity is inhibited. Upon mTORC1 activation, phosphorylated S6K1 dissociates from the eIF3 complex and begins phosphorylating its multiple substrates required for translation initiation as well as other steps in protein production (Holz *et al.*, 2005). For example, S6K1 phosphorylates eIF4B on Ser422 and stimulates its function to enhance eIF4A, an essential mRNA helicase that unwinds the secondary structure in the 5'-untranslated region (5'UTR) of mRNA for efficient translation initiation (Raught *et al.*, 2004). S6K1 also phosphorylates Ser67 of an inhibitor of eIF4A, programmed cell death 4 (PDCD4), thereby further enhancing eIF4A helicase activity (Dorrello *et al.*, 2006). In addition, S6K1 stimulates eukaryotic translation elongation factor 2 (eEF2), which plays an important role in translation elongation, by inhibiting its upstream negative regulator, eEF2 kinase through direct phosphorylation (Ser366) (Wang *et al.*, 2001). S6K1 phosphorylates ribosomal protein S6 (rpS6) on multiple sites (Ser235, Ser236, Ser240, and Ser244). However, the functional significance of rpS6 phosphorylation remains unclear (Ruvinsky *et al.*, 2005). S6K1 also phosphorylates and activates Skar, an important protein that catalyzes splicing of mRNAs (Richardson *et al.*, 2004). In addition to its role in the regulation of translation, S6K1 also phosphorylates Insulin Receptor Substrate 1 (IRS1), leading to destabilization and degradation of this substrate, thereby providing negative feedback for the PI3K-Akt pathway (Harrington *et al.*, 2004; Um *et al.*, 2004; Shah *et al.*, 2004).

e4EBPs such as 4EBP1 are also well-characterized mTORC1 substrates (Gingras *et al.*, 2001). In the absence of mTORC1 activation, hypo-phosphorylated 4EBP1 binds to and represses eIF4E, which directly interacts with the 5'-cap of mRNAs (Pause *et al.*, 1994; Richter and Sonenberg, 2005). Upon mTORC1 activation, mTORC1 binds to eIF3 and phosphorylates 4EBP1 on several sites (e.g., Thr37, Thr46, Thr70, and Ser65) (Gingras *et al.*, 1999). mTORC1-mediated 4EBP1 phosphorylation induces the dissociation of 4EBP1 from eIF4E and allows eIF4E to interact with eIF4G1/3, key adaptor proteins that interact with other initiation factors to form the active eIF4F complex (Gross *et al.*, 2003; Richter and Sonenberg, 2005).

Grb10 Is a Newly Identified mTORC1 Substrate

Although the mTORC1-mediated phosphorylation of S6K1 and 4EBP1 has been widely regarded as the gold standards for measuring cellular mTORC1 activity, mTORC1 regulates a wide array of cellular processes in addition to its role in translation. Recent large-scale phospho-proteomics studies provided a potent strategy for the identification of novel mTOR substrates. By comparing the phospho-protein profiles in the presence or absence of mTOR inhibitors, two groups independently identified Grb10 as a novel substrate for mTORC1 (Hsu *et al.*, 2011; Yu *et al.*, 2011). Grb10 binds to

and negatively regulates insulin receptors and IGF receptors (Wick *et al.*, 2003). mTORC1 phosphorylates Ser501 and Ser503 on Grb10 to promote protein stability. By phosphorylating and stabilizing Grb10, mTORC1 negatively regulates the insulin receptor-PI3K-Akt pathway, which provides another mechanism for negative feedback regulation in addition to S6K1-mediated IRS inhibition.

Sterol-Regulatory-Element-Binding Proteins Bridge mTORC1 to Lipid Synthesis

In agreement with its role as a master regulator of anabolism, mTORC1 also plays a fundamental role in lipid synthesis (Lamming and Sabatini, 2013) by regulating the cellular levels of many lipogenic genes. Sterol-regulatory-element-binding proteins (SREBPs) are transcription factors responsible for the expression of enzymes important for fatty acid and sterol synthesis (Horton *et al.*, 2002). mTORC1 stimulates the function of SREBPs at multiple steps by: (1) enhancing the mRNA and protein expression of SREBPs (Wang *et al.*, 2011; Yecies *et al.*, 2011); (2) promoting the processing of the SREBP precursor to the mature form and enhancing its nuclear localization (Yecies *et al.*, 2011; Duvel *et al.*, 2010; Owen *et al.*, 2012); and (3) phosphorylating and inhibiting Lipin1, a negative regulator of SREBPs (Peterson *et al.*, 2011). The identification of mTORC1 as a regulator of SREBPs explains how lipid synthesis is intimately coupled to the levels of cellular nutrient availability and growth factor signaling.

Transcription Factor EB Mediates the Effect of mTORC1 on Lysosome Biogenesis

mTORC1 controls lysosome biogenesis through its regulation of the bHLH leucine zipper transcription factor EB (TFEB). TFEB is a major transcription factor that stimulates transcription of genes encoding proteins related to lysosome biogenesis and autophagy (Sardiello *et al.*, 2009). Recent studies identified mTORC1 as an upstream regulator of TFEB (Roczniaik-Ferguson *et al.*, 2012; Settembre *et al.*, 2012; Martina *et al.*, 2012; Pena-Llopis *et al.*, 2011). In the nutrient-rich conditions where mTORC1 is active, TFEB is directly phosphorylated by mTORC1 at the lysosome membrane. Phosphorylated TFEB is sequestered in the cytoplasm through its interaction with 14-3-3 proteins, thus inhibiting the expression of genes required for lysosome and autophagy biogenesis. Conversely, in mTORC1 inactive conditions, non-phosphorylated TFEB translocates into the nucleus, where it stimulates lysosomal and autophagic gene expression. Intriguingly, however, transcript levels of TFEB and its target genes are enhanced in MEFs lacking functional TSC2, a key suppressor of mTORC1 (Pena-Llopis *et al.*, 2011). These observations suggest that the effect of chronic and acute mTORC1 activation on TFEB activity may not be the same.

mTORC1 Suppresses Autophagy

mTORC1 is a major suppressor of autophagy induction (Jung *et al.*, 2010; Rubinsztein *et al.*, 2007). Autophagy is an

evolutionarily conserved catabolic process in which unnecessary, dysfunctional, or toxic cellular material are captured and delivered by double-membrane autophagic vesicles (autophagosomes) to the lysosome for degradation (Rabinowitz and White, 2010; Mizushima *et al.*, 2008; Levine and Kroemer, 2008). Inhibition of mTORC1 by rapamycin stimulates the induction of autophagy even in nutrient-rich conditions where autophagy is typically repressed (Noda and Ohsumi, 1998). mTORC1 inhibits autophagy by phosphorylating several proteins required for autophagy induction. The ULK1-Atg13-FIP200 complex is required at the initial step of autophagosome formation. Under nutrient-rich conditions, mTORC1 interacts with the ULK1-Atg13-FIP200 complex and phosphorylates Atg13 and ULK1 kinases to inhibit their kinase activity, thereby mitigating autophagy induction. Under starvation or rapamycin treatment conditions, inactive mTORC1 dissociates from this complex. This leads to dephosphorylation and activation of ULK1, which promotes ULK1-dependent phosphorylation of Atg13 and FIP200, processes essential for autophagy induction (Ganley *et al.*, 2009; Hosokawa *et al.*, 2009; Jung *et al.*, 2009). A recent study indicated that AMPK, a key cellular energy sensor and activator of autophagy (Egan *et al.*, 2011), directly antagonizes mTORC1-mediated inactivation of ULK1 in the ULK1-Atg13-FIP200 complex to stimulate autophagy (Kim *et al.*, 2011). During energy shortage, active AMPK promotes autophagy by phosphorylating Ser317 and Ser777 of ULK1. In contrast, under nutrient-rich conditions, active mTORC1 phosphorylates ULK1 on Ser757, which causes the dissociation of AMPK from ULK1 (Kim *et al.*, 2011). In this regard, the ULK1-Atg13-FIP200 complex functions as a hub to transmit upstream signals that reflect cellular nutrient availability to downstream regulation of autophagy induction.

Upstream of mTORC1

Regulation of mTOR Signaling by Growth Factors

Growth factor-induced mTORC1 activation

Growth factors, such as insulin and insulin-like growth factor 1, exert strong anabolic effects and play crucial roles in promoting cell growth, proliferation, survival, and metabolism. Growth factors bind and activate the receptor tyrosine kinases, such as insulin receptor and IGF receptor, thereby engaging and activating the PI3 kinase and Akt (Alessi *et al.*, 1997). Akt mediates upstream of mTORC1 and leads to mTORC1 activation via two approaches. The first approach goes through the TSC-Rheb axis (Manning and Cantley, 2003). The tuberous sclerosis complex (TSC) is composed of TSC1, TSC2, and TBC1D7 (van Slegtenhorst *et al.*, 1998; Dibble *et al.*, 2012). TSC2 functions as a GTPase-activating protein (GAP) for the Rheb GTPase, a direct stimulator of mTORC1 (Manning and Cantley, 2003; Wulfschleger *et al.*, 2006), while TSC1 and TBC1D7 support TSC2 function by stabilizing TSC2 protein and facilitating its GAP activity toward Rheb, respectively. Thus, active TSC complex functions as a key suppressor of Rheb, while Rheb directly interacts with and stimulates mTORC1 activity (Sancak *et al.*, 2007; Long *et al.*, 2005). Previous biochemical and genetic studies demonstrated that Akt directly

phosphorylates and inhibits TSC2 function to stimulate Rheb-mTORC1 activity (see later section) (Figure 1). The second approach depends on PRAS40, a suppressor of mTORC1 (Sancak et al., 2007; Vander Haar et al., 2007). Akt phosphorylates PRAS40 on Thr224 (Sancak et al., 2007; Vander Haar et al., 2007), which decreases the binding affinity of PRAS40 for mTORC1, thereby relieving its inhibitory effect on mTORC1 activity.

In addition to Akt, Erk1/2 and RSK1 also mediate the positive effects of growth factors on mTORC1 activity through TSC (Ma et al., 2005; Roux et al., 2004). In response to growth factor stimulation, Erk1/2 phosphorylates TSC2 on Ser664, while RSK1 phosphorylates TSC2 on Ser1798. These phosphorylations lead to the inactivation of TSC2 and the activation of mTORC1. TNF signaling also activates mTORC1. IKK β , a major downstream kinase in the TNF α signaling pathway, physically interacts with and phosphorylates TSC1 at Ser487 and Ser511, resulting in suppression of the function of the TSC complex (Lee et al., 2007). Through control of the TSC-Rheb axis, the growth factor pathway and TNF pathways positively regulate mTORC1 activity.

Growth factor-induced mTORC2 activation

Similar to mTORC1, mTORC2 activation is also stimulated by growth factors-PI3K signaling. However, the exact mechanisms by which mTORC2 is activated by growth factor-PI3K signaling remains to be fully understood. By genetic screening in yeast, Zinzalla et al. (2011) found that ribosomes are required for TORC2 signaling. The observations in mammalian systems indicate that this mechanism is also conserved in mammals. Knocking down NIP7, which is required for ribosomal 60S subunit maturation, or knocking down large or small ribosome subunit proteins, invariably reduces mTORC2 activation by growth factors. Active mTORC2 physically associates with the ribosome, and insulin stimulation enhances this association in a manner dependent on PI3K activity. Because the capacity of cell growth and proliferation mainly depend on the contents of ribosomes, this study first proposed a novel mechanism by which a component that reflects cellular anabolic capacity is coordinated with extracellular stimuli to stimulate mTORC2 activity.

Regulation of mTOR Signaling by Energy

Essential cellular anabolic processes such as ribosome biogenesis, mRNA translation, and protein synthesis all consume energy and, accordingly, mTORC1 activity is sensitive to and finely tuned by levels of cellular energy. AMP-activated protein kinase (AMPK) is a major regulator of cellular and organismal energy homeostasis. It coordinates multiple metabolic pathways to balance energy supply and demand to ultimately modulate cell and organ growth. In the context of mTORC1 signaling, AMPK acts as an important suppressor of mTORC1 (Figure 1). When cellular energy level is low, active AMPK phosphorylates and activates TSC2, which leads to the inactivation of mTORC1 (Inoki et al., 2003). AMPK phosphorylates also Raptor on two well-conserved serine residues, Ser722 and Ser792, and inhibits mTORC1 (Gwinn et al., 2008). The phosphorylation of Raptor induces its binding

to the 14-3-3 protein and PRAS40, a negative regulator of mTORC1. The phosphorylation of Raptor by AMPK is also required for cell-cycle arrest induced by energy stress. A recent study indicates that cellular glucose levels also regulate mTORC1 activity. Glucose deprivation triggers the p38 MAPK-PRAK pathway and induces PRAK to phosphorylate Ser130 of the Rheb small GTPase. Rheb phosphorylation reduces its binding to guanine nucleotides (Zheng et al., 2011), thus attenuating GTPase function and its ability to activate mTORC1.

Regulation of mTOR Signaling by Cellular Stress

TSC collects various stress signals to suppress mTORC1

Hypoxia suppresses mTORC1 activity (Brugarolas et al., 2004). Oxygen is an essential regulator of cellular metabolism. Under hypoxic conditions, cells promptly activate a variety of adaptive responses that limit energy expenditure through inhibition of energy-intensive processes including protein synthesis. Inhibition of mTORC1 activity is observed when cells are exposed to the low oxygen, and mTORC1 inhibition under hypoxic conditions depends on REDD1 and TSC (DeYoung et al., 2008; Brugarolas et al., 2004). REDD1 (also known as RTP801/Dig1/DDIT4) is a member of a gene family that includes its paralog REDD2 (RTP801L, DDIT4L) and the *Drosophila* orthologs *Scylla* and *Charybdis* (Ellisen et al., 2002). Like the *Drosophila* orthologs, mammalian REDD1/2 are highly induced at the transcription level in response to a variety of stresses, including DNA damage, dexamethasone, and hypoxia (Corradetti et al., 2005). Subcellular localization of the TSC complex is critical to its signaling function (see later section). The 14-3-3 proteins have been reported to bind Akt-phosphorylated TSC2 and inhibit the function of TSC2 presumably through altering its subcellular localization. Redd1 and Redd2 stimulate TSC2 activity by repelling its association with 14-3-3 thereby inhibiting mTORC1. However, the precise molecular mechanisms by which Redd1/2 specifically block 14-3-3 association with TSC2 without affecting levels of TSC2 phosphorylation remain to be elucidated (DeYoung et al., 2008; Li et al., 2002).

Regulation of mTORC1 by stress granules

Recent studies suggest that the subcellular localization of mTORC1 is dynamically regulated and determines cellular mTORC1 activity in response to various stresses. Interestingly, the formation of RNA granules under stress conditions appears to be an important process to inhibit mTORC1 activity. RNA granules are cytosolic non-membrane bound compartments that consist of mRNAs and their associated proteins (i.e., mRNPs) (Anderson and Kedersha, 2006). A repertoire of mRNPs determines whether mRNP complexes remain silent, become translationally active, or are degraded (Buchan and Parker, 2009). Under stress conditions such as heat, oxidative and osmotic stress, virus infection, and UV irradiation, translationally silenced mRNPs accumulate in stress granules (SGs) (Anderson and Kedersha, 2008). Studies in *Saccharomyces cerevisiae* have shown that TORC1 partitions in heat-induced SGs, suggesting a physiological role of SGs in the spatiotemporal regulation of mTORC1 activity during stress (Takahara and

Maeda, 2012). Studies in mammalian cells indicate that the dual specificity tyrosine phosphorylation-regulated kinase 3 (DYRK3) plays important roles in regulating SGs dissolution and mTORC1 localization in SGs (Wippich *et al.*, 2013). When DYRK3 is active, it promotes SG dissolution and concomitantly releases mTORC1 into the cytosol, a process important for mTORC1 activation during recovery from cellular stress. In contrast, inactive DYRK3 protects SG formation and sequesters mTORC1 within SGs, thereby inhibiting mTORC1 activity in stress conditions. Furthermore, active DYRK3 directly phosphorylates PRAS40 and relieves its inhibition of mTORC1 activity, providing yet another biochemical mechanism by which DYRK3 activates mTORC1. Interestingly, another study proposed that the formation of SGs inhibits mTORC1 activity in a different manner. Thedieck *et al.* (2013) identified astrin as a novel mTORC1 binding protein. Astrin was originally identified as a kinetochore- and microtubule-associated protein, that functions to maintain microtubule-centromere attachment and separation (Mack and Compton, 2001; Thein *et al.*, 2007). Astrin is also recruited to SGs under cellular stress conditions such as arsenite treatment. Under such metabolic stress conditions, astrin interacts with Raptor and disrupts mTORC1. Thus, sequestration of Raptor within SGs through astrin decreases cellular mTORC1 activity under acute stress conditions (Thedieck *et al.*, 2013). Uncontrolled hyperactivation of mTORC1 is often observed in cancer cells and cells lacking functional TSC complex. In these cells, abundant energy is required for maintaining their cellular anabolisms. Lack of sufficient energy caused by aberrant mTORC1 activation in cancer cells or TSC-null cells causes cell death under severe stress conditions. Therefore, astrin-mediated inhibition of mTORC1 may be one mechanism underlying the anti-apoptotic nature of SG formation in these cells. Consistent with this hypothesis, the expression of astrin is enhanced in certain types of cancer cells. Thus, inhibition of aberrant mTORC1 activation through SG formation may represent a self-defense mechanism in certain cancer cells.

Genotoxic stresses suppress mTORC1

Genotoxic stress, such as DNA damage, also suppresses mTORC1 activity. DNA damage activates the major tumor suppressor p53, which blocks cell cycle progression for cell survival or executes apoptotic cell death (Levine, 1997). In addition, p53 also inhibits cell growth by attenuating certain anabolic processes including protein synthesis, a major energy consuming process, to maintain energy homeostasis under stress conditions (Vousden and Lane, 2007). Genotoxic stresses-induced p53 has been proposed to inhibit mTORC1 activity through the up-regulation of its upstream negative regulators such as PTEN, TSC2, and AMPK β 1 (Feng *et al.*, 2007). Two other genes, sestrin1 and sestrin2, have also been recently identified to mediate DNA damage-induced mTORC1 inhibition (Budanov and Karin, 2008). Both sestrin1 and sestrin2 are transcriptionally induced by p53 under stress conditions. Interestingly, enhanced expression of sestrins is capable of activating AMPK and inhibiting mTORC1 activity. Although the molecular mechanisms by which sestrins activate AMPK remain to be fully understood, many metabolic stresses converge on AMPK activation to attenuate cellular mTORC1 activity.

Regulation of mTOR Signaling by Amino Acids

Amino acids are essential for the activation of mTORC1, but not mTORC2. While it has been known for years that amino acids have crucial roles in mTORC1 activation, the exact molecular mechanisms had remained largely unknown until recently. The studies from several laboratories first discovered that evolutionarily conserved small GTPases, GTR1/2 in yeast and Rags in mammals, are required for amino acid-mediated regulation of mTORC1 (Sancak *et al.*, 2008; Kim *et al.*, 2008; Figure 2). Mammalian Rags, which belong to the Ras-related small GTPase family, consist of four proteins, RagA, B, C, and D, and localize on the lysosomal membrane. Rags form obligate heterodimers of either RagA or RagB with either RagC or RagD. Two members of the heterodimers have opposing nucleotide-loading states. In the state where RagA or RagB binds to GTP while RagC or RagD binds to GDP, the complex has its maximum activity and interacts with Raptor (Efeyan *et al.*, 2012). Upon amino acid stimulation, RagA or RagB binds GTP and the active Rag heterodimer recruits mTORC1 to the lysosomal membrane through its interactions with Raptor (Sancak *et al.*, 2008). Interestingly, accumulation of amino acids in the lysosomal lumen is required for triggering mTORC1 recruitment via the activation of the Rag heterodimer, proposing a lysosome-centric 'inside-out' model of amino acid sensing (Zoncu *et al.*, 2011). Sabatini and coworkers identified a series of key mechanisms by which the accumulation of amino acids in the lysosomal lumen stimulates Rag GTPases. These studies demonstrate that the vacuolar H⁺-adenosine triphosphate ATPase (V-ATPase) functions as a sensor for luminal amino acids and interacts with the Ragulator complex. Ragulator is a pentameric protein complex that includes the mitogen-activated protein kinase scaffold protein 1 (MP1), p14, and p18. Importantly, Ragulator resides on the late endosome/lysosome surface through p18, which has myristoylation and palmitoylation sites near its N-terminus (Nada *et al.*, 2009; Figure 2). Ragulator possesses dual functions in regulating Rags by working not only as a scaffold to anchor Rag heterodimers to the lysosome, but also as a guanine exchange factor (GEF) for RagA and RagB (Bar-Peled *et al.*, 2012). Consistently, loss of Ragulator complex components disperses the Rags from the lysosome to the cytosol and disables the lysosome recruitment of mTORC1 under amino acid-enriched conditions (Sancak *et al.*, 2010). Upon amino acid stimulation, the GEF activity of Ragulator promotes loading of RagA or B with GTP in a v-ATPase-dependent manner, which enables RagA or B to interact with Raptor in mTORC1. Taken together, these studies reveal an important role for the lysosome as an amino acids sensing organelle to initiate cellular anabolic processes through mTORC1 activation in addition to its function as a degradation and recycling center (Figure 2).

Akin to the function of the TSC complex as a GAP that inhibits the Rheb small GTPase and mTORC1 activity, RagA/B small GTPases are also subject to GAP-dependent inhibition. Bar-Peled *et al.* (2013) identified a specific GAP for RagA/B in mammalian cells. The GAP for RagA/B also exists as a multi-protein complex, termed GATOR (GAP activity toward Rags), and its functional counterparts are conserved in yeast (Panchaud *et al.*, 2013). The GATOR complex consists of at

Figure 2 Spatial regulation of mTORC1 on the lysosomal membrane. Under low amino acid and growth factor conditions (left panel), the Rag heterodimer is inactivated, and mTORC1 is not recruited on the lysosomes. The TSC complex, which associates with inactive Rag heterodimer, inhibits Rheb activity. Upon amino acid stimulation (right panel), the Rag heterodimer anchored at the lysosomal membrane through Ragulator recruits mTORC1 to the lysosomes. Concomitantly, Akt stimulated by growth factors phosphorylates TSC2 and dissociates the TSC complex from the lysosomal membrane, thereby inducing Rheb activity on the lysosomal membrane. The active Rheb then stimulates mTORC1 on the lysosomes.

least eight proteins that can be divided into two sub-complexes, GATOR1 and GATOR2. Interestingly, GATOR1 (DEPDC5, Nprl2, and Nprl3) and GATOR2 (Mios, WDR24, WDR59, Seh1L, and Sec13) exert opposite effects on amino acid-induced mTORC1 activity: loss of GATOR1 subunits renders mTORC1 insensitive to amino acid starvation whereas inhibition of GATOR2 subunits suppresses mTORC1 activity. Further experiments showed that mTORC1 inhibition induced by loss of functional GATOR2 was rescued by additional deletion of GATOR1 components, indicating that GATOR2 negatively regulates GATOR1. As yeast homologs of GATOR1 have GAP activity toward Gtr1, a mammalian RagA/B ortholog, GATOR1 exerts specific GAP activity for RagA/B but not for RagC/D.

Recent studies also revealed that folliculin (FLCN), a tumor suppressor mutated in Birt-Hogg-Dube syndrome, with its interacting protein, FNIP1, function together as the RagC/D GAP (Petit *et al.*, 2013; Tsun *et al.*, 2013). For mTORC1 activation, GDP-bound RagC/D is active and necessary for the interaction between mTORC1 and the Rag heterodimer. These observations indicate that the FLCN-FNIP1 complex is an essential regulator in amino acid-induced mTORC1 activation. However, it is puzzling that a tumor suppressor such as FLCN supports mTORC1 activation, which is often observed as hyper-activated in many cancers. Indeed, mice lacking FLCN expression in heart tissue display cardiac hypertrophy with increased mTORC1 activity (Hasumi *et al.*, 2014). There are also mixed reports regarding the function of FLCN in the regulation of AMPK signaling. FLCN has been reported to interact with AMPK. In *Caenorhabditis elegans* and a human follicular thyroid carcinoma cell line, FLCN acts as a suppressor for AMPK (Possik *et al.*, 2014; Yan *et al.*, 2014); however, it functions as a positive regulator for AMPK in murine cardiac myocytes and mammary gland epithelial cells

(Goncharova *et al.*, 2014). These observations suggest that FLCN may regulate multiple steps of different nutrient sensing pathways in a positive or negative manner in order to maintain cellular energy homeostasis.

mTORC1 Associates with Rheb on Lysosomal Membranes

Amino acids and growth factors are two indispensable inputs for mTORC1 activation: lack of either one of these inputs diminishes cellular mTORC1 activation. However, the mechanism by which these essential signals are coordinated to fully activate mTORC1 has not been well understood. Amino acid-induced recruitment of mTORC1 to lysosomal membranes by Rag small GTPases predicts that lysosomal mTORC1 should also associate with Rheb, a direct activator for mTORC1. A study by Sancak *et al.* first reported this hypothesis by demonstrating that amino acid-dependent lysosomal localization of mTORC1 is required for Rheb-induced mTORC1 activation (Figure 2; Sancak *et al.*, 2008). They and others demonstrated that Rheb, which is activated by growth factors through the PI3K-Akt-TSC pathway, resides on the lysosome (Saito *et al.*, 2005; Menon *et al.*, 2014; Sancak *et al.*, 2008). The localization of Rheb to the lysosomal membrane depends on farnesylation of Rheb at its C terminal CAAX motif (Clark *et al.*, 1997). The GTP-bound form of Rheb directly interacts with mTORC1 and stimulates its kinase activity (Long *et al.*, 2005), although the precise molecular mechanism by which active Rheb enhances mTORC1 kinase activity is not fully understood. Nevertheless, these studies indicate that the surface of the lysosome provides a platform where two essential signals, amino acids and growth factors, converge to stimulate mTORC1. This model established by Sancak *et al.* raises the obvious question of how Rheb activity is regulated by growth factor signaling on lysosomes.

More recently, two groups demonstrated that the TSC complex, which is the Rheb GAP and a major upstream negative regulator of mTORC1, also localizes on lysosomes in a regulated manner (Menon *et al.*, 2014; Demetriades *et al.*, 2014; Figure 2). Interestingly, Menon and colleagues demonstrated that TSC2 dissociates from lysosomal membranes in response to insulin stimulation in a manner dependent on its phosphorylation by Akt. The phospho-defective TSC2 mutant, which cannot be phosphorylated by Akt, displays constitutive lysosomal localization and inhibitory activity even in the presence of growth factors. In PTEN deficient cancer cells where the PI3K-Akt pathway is constitutively active, Menon and colleagues further demonstrated that TSC2 remains dissociated from the lysosome, leading to constitutively active mTORC1. These observations suggest that growth factor-mediated spatial regulation of the TSC complex on lysosomes plays an essential role in modulating mTORC1 activity.

Interestingly, Demetriades and colleagues proposed that the TSC complex functions on lysosomes downstream of the nutrient-sensing pathway. TSC2 is capable of binding to RagA, and this binding depends on both an N-terminal motif and a five amino-acid C-terminal motif unique to RagA but not RagB. Upon amino acid withdrawal, TSC2 is recruited to lysosomes through the interaction with GDP-bound inactive RagA (Figure 2). Furthermore, ablation of functional Rag heterodimer on the lysosome by knocking down either RagA or Ragulator or the activation of RagA by knocking down of GATOR1 abolishes lysosomal localization of TSC2 under amino acid deprivation conditions (Sancak *et al.*, 2010; Bar-Peled *et al.*, 2013; Demetriades *et al.*, 2014). These observations indicate that inactive RagA determines TSC2 localization on the lysosomes, where TSC2 inhibits Rheb. In addition, Demetriades *et al.* demonstrated that mTORC1 does not completely dissociate from lysosomes upon amino acid starvation when active Rheb is still localized on lysosomes in TSC2 null cells. Consistently, higher mTORC1 activity could be detected in TSC2 null cells even under amino acid starved conditions. Similar observations were also made by Gao *et al.* in an earlier study (Gao *et al.*, 2002). These data suggest that complete release of mTORC1 from lysosomes requires inactivating both Rags and Rheb. Although some differences exist, these two studies propose two independent and important mechanisms by which localization of the TSC complex is regulated by either growth factor or amino acids with the lysosome serving as a central platform for the recruitment and activation of mTORC1.

Concluding Remarks

Recent studies have made great strides in our understanding of the molecular events by which numerous upstream signals coordinately stimulate or repress mTORC1 activity in response to various cellular cues. Such progress naturally gives rise to new questions in the field. As with other Ras-related small GTPases, the two essential small GTPases, Rag and Rheb, which directly regulate mTORC1, are themselves tightly regulated by their specific GAPs and GEFs. Recent studies have identified all of the key GAP proteins for Rheb, Rag A/B, and RagC/D. However, only the GEF for RagA/B was identified,

raising the question of whether GEFs for RagC/D or Rheb exist. In addition, it remains to be fully understood how amino acids coordinately regulate multiple GAPs (GATOR1 and FLCN) and GEF (Ragulator) for Rags. Although considerable evidence clearly indicates the importance of these GAPs and GEF for Rag guanyl nucleotide binding, there is little data demonstrating that cellular amino acid levels indeed alter the guanyl nucleotide charging of RagA/B or RagC/D. A recent study from the Avruch group demonstrated that withdrawal of extracellular amino acids does not alter Rag guanyl nucleotide charging, although it clearly decreases the Rag-mTORC1 interaction and cellular mTORC1 activity (Oshiro *et al.*, 2014). The authors speculated that additional factors that respond to amino acid sufficiency might bridge Rag and mTORC1 binding to enhance mTORC1 activity. Interestingly, more recent studies demonstrated that cells lacking RagA, the major mammalian homologs of yeast GTR1p, maintain an intact response to insulin for mTORC1 activation. Furthermore, in the RagA null MEFs, mTORC1 activity is maintained although mTORC1 activation or inactivation in response to amino acid stimulation or withdrawal, respectively, is significantly compromised compared to RagA expressing MEFs (Efeyan *et al.*, 2014). More intriguingly, mTORC1 activity in heart tissues lacking both RagA and RagB is not significantly changed compared to that in control heart tissues (Kim *et al.*, 2014). These observations raise the possibility that there may be additional mechanisms underlying amino acid-induced mTORC1 activation.

Another unresolved question is where mTORC1 is localized under amino acid starvation conditions and where mTORC1 phosphorylates its multiple, distinct substrates. In amino acid-deprived cells, mTOR is distributed in punctate structures throughout the cytoplasm. In contrast, upon amino acid stimulation, mTOR localizes on lysosomes while its major substrates, such as S6K1 and 4EBP1, remain diffusely distributed throughout the cytoplasm with mRNPs. Therefore, how can activated mTORC1 sequestered on lysosomal membranes contact and phosphorylate its substrates that are diffusely localized throughout the cytoplasm? One possibility is that mTORC1 primed on the surface of lysosomes or other cytoplasmic membrane compartments dissociates from these membrane platforms to gain access to its substrates in a Rag- and/or Rheb-dependent manner. Consistent with this hypothesis, sucrose density sedimentation assays reveal that the vast majority of mTORC1 as well as Rags fractionate in cytoplasmic fractions under amino acid sufficient conditions (Oshiro *et al.*, 2014). However, these subcellular fractionation experiments are inconsistent with immunocytochemistry findings that show the majority of mTOR and Rags localized to lysosomal membranes under amino acid sufficient conditions. One concern is that many laboratories in the field, including ours, use the same antibodies to detect mTOR and Rag for immunolocalization studies. It is possible that these antibodies preferentially recognize mTOR and Rag epitopes only when these factors are configured on lysosomal membranes, an idea that should be easily testable. Furthermore, the identification of additional factors that interact with Rag-mTORC1 and Rheb and the development of new methodologies to track the *in vivo* movements of mTORC1 with single-molecule precision will allow us to answer many of these remaining

questions in the field while generating the next wave of questions in the mTOR signaling pathway.

Nucleolar Architecture

Nucleoli are formed and maintained in a self-organizing fashion and are not bound by a membrane (Figure 1; Boisvert *et al.*, 2007; Sirri *et al.*, 2008; Shaw and Brown, 2012; Raska *et al.*, 2006). Nucleolar architecture and function are intimately linked (Stoykova *et al.*, 1985). The prevailing view is that nucleolar architecture is a consequence of the complex, dynamic processes involved in ribosomal RNA (rRNA) synthesis, processing, and ribosome subunit assembly (Melese and Xue, 1995). For example, during each cell division cycle, nucleoli are disassembled upon entry into mitosis and do not reassemble until after transcription is reestablished at the end of mitosis (Leung *et al.*, 2004).

Nucleoli form around clusters of ribosomal DNA (rDNA) genes, so called nucleolar organizing regions (NORs) (Hernandez-Verdun, 2011). Although somatic cells sharing the same genome contain an identical number of NORs, nucleoli can vary in size, shape, and number in different tissues within the same organism. Comparison of nucleoli in human cell lines derived from an embryonal carcinoma and an osteosarcoma, as shown in Figure 2, provides an illustrative example of the wide range of nucleolar morphologies.

The human nucleolus is arranged in a tripartite structure (Movie 1). Individual subnucleolar regions can be distinguished based on differences in contrast when viewed with transmission electron microscopy (TEM). As shown in the electron micrograph in Figure 3, three unique subcompartments are visible in human nucleoli: the fibrillar centre (FC), the dense fibrillar component (DFC), and the granular

component (GC). Immunofluorescence microscopy of selected markers can also be used to visualize the three nucleolar subcompartments, as shown in Figure 4 (Movie 1).

Nucleoli and Ribosome Subunit Biogenesis

Each nucleolar compartment is closely associated with specific steps in ribosome subunit biogenesis as illustrated in Figure 5.

Figure 2 The size, shape, and number of nucleoli is cell-type dependent. This image compares two human cell lines derived from different types of tissues and cancer. Tera-1 cells, which are derived from a metastasis of an embryonic carcinoma of the testes, typically have a single large nucleolus. In contrast, U2OS cells, which are derived from an osteosarcoma of the bone, typically have several smaller nucleoli. Nucleoli were stained with an antinucleolin antibody (red) and DNA was stained with 4',6-diamidino-2-phenylindole (DAPI) (blue). Arrows indicate nucleoli (labeled in red).

Figure 1 The nucleolus. (a) Nucleoli can be easily observed using differential interference contrast microscopy in cells as high contrast spheroids (representative nucleolus indicated by arrow) in the nucleus. This image shows human osteosarcoma (U2OS) cells. (b) Nucleolar architecture can also be visualized by transfection with a plasmid coding for a green fluorescent protein (GFP)-tagged nucleolar protein (fibrillarin shown here) and visualized under a fluorescence microscope. (c) Overlay of (a) and (b). DIC, Differential interference contrast.

Figure 3 The tripartite structure of human nucleoli. TEM of human nucleoli reveals three nucleolar subcompartments that differ in TEM contrast: fibrillar centers, the DFC, and the GC. The nucleolus is also surrounded by heterochromatin.

Each ribosome is a ribonucleoproteic ribozyme made up of a large 60S subunit and a small 40S subunit, both of which only assemble into a full ribosome once recruited on a mature mRNA for translation. In humans the 60S subunit comprises the 28S, 5.8S, and 5S rRNAs and 47 proteins, while the 40S subunit comprises the 18S rRNA and 33 proteins (for a review of ribosome composition and structure, see [Yusupova and Yusupov, 2014](#)). The 28S, 18S, and 5.8S rRNAs are derived from cleavage and processing of a common precursor, the 47S rRNA, which is synthesized by transcription of rRNA genes by the RNA Pol I machinery. It is generally assumed that this

process takes place either at the border between the FC and DFC or within the FC. In contrast to the 47S rRNA, the 5S rRNA is transcribed in the nucleoplasm by RNA Pol III. The ribosomal proteins are generally small, basic proteins with large spans of unstructured loops, which are thought to become stabilized in ribosomes by interactions with rRNA (reviewed in [Korobeinikova et al., 2012](#)). The mRNAs that encode ribosomal proteins are synthesized by RNA Pol II. Thus, ribosome subunit biogenesis involves all three cellular transcription machineries (RNA Pol I for 47S rRNA, RNA Pol II for ribosomal protein mRNAs, and RNA Pol III for 5S rRNA).

Figure 4 Immunofluorescence microscopy of the tripartite nucleolar architecture in human U2OS cells. Proteins in the FC, such as UBF, are concentrated in punctate bodies within nucleoli. Proteins in the DFC, such as fibrillarin, appear as slightly larger punctate bodies surrounding the FC. Proteins in the GC, such as B23/nucleophosmin, are heterogeneously diffuse within nucleoli. Stacks of 2D images have been reconstructed to produce a movie showing the tripartite nucleolar architecture in 3D, which is available here (Movie 1).

Figure 5 Illustration of ribosome subunit biogenesis in mammalian nucleoli. Transcription of rDNA occurs at active rDNA loci within the FC or at the edge of the FC/DFC. Nascent rRNA is then processed and modified in a number of ways, including cleavage, 2'-O-methylation and pseudouridination, by snoRNPs and protein-processing factors. The pre-40S and pre-60S ribosome subunits are assembled in the DFC and GC before release from the nucleolus. Final processing steps occur in the nucleoplasm prior to transport into the cytoplasm.

Once synthesized, the 47S is cleaved into 18S, 28S, and 5.8S rRNAs within the nucleolus. Factors responsible for cleavage of 47S rRNA and further posttranscriptional modifications of rRNA, such as methylation of specific base and ribose residues, and pseudouridylation, are concentrated within the DFC (for further details refer [Watkins and Bohnsack, 2012](#)). Methylation of ribose 2'-hydroxyl groups (2'-O-methylation) and conversion of uridine to pseudouridine are

guided by small nucleolar RNAs (snoRNAs) as part of small nucleolar ribonucleoprotein (snoRNP) complexes. Two classes of snoRNAs exist, the box C/D type (involved in 2'-O-methylation) and the H/ACA snoRNAs (responsible for pseudouridylation), which are distinguished by the presence of typical sequence motifs, or boxes that interact by Watson-Crick pairing with sequences to be modified (for more details on snoRNAs see [Bratkovic and Rogelj, 2014](#)). Numerous

individual modifications in rRNA are known and these are crucial for ribosome function (Watkins and Bohnsack, 2012). The Fournier laboratory has assembled a 3D ribosomal modification database as an interactive tool to visualize position and consequences of rRNA modifications (Piekna-Przybylska *et al.*, 2008; see Relevant Websites Section – University of Massachusetts Amherst).

Eventually, processed 18S, 28S, and 5.8S rRNAs are assembled with the 5S rRNA and ribosomal proteins in the GC, thus forming pre-40S and pre-60S ribosome subunits. Final processing steps, resulting in mature ribosomal subunits able to participate in translation, occur after export into the cytoplasm (reviewed in Panse and Johnson, 2010).

Ribosomal DNA

In human cells, NORs are located on the short arms (p arms) of the acrocentric chromosomes (chromosomes 13, 14, 15, 21, 22 in human) (Henderson *et al.*, 1972). As rDNA is ~10 times less condensed than neighboring DNA, NORs are visible on metaphase chromosomes as structures called secondary constrictions (as opposed to ‘primary constrictions,’ i.e., centromeres) (Heliot *et al.*, 1997). Due to the continuous presence of specific acidic/argyrophilic proteins at rDNA, even throughout mitosis, NORs can also be visualized by silver staining (Goodpasture and Bloom, 1975; Roussel *et al.*, 1996). A complementary approach to detect rDNA loci is DNA FISH

(fluorescence *in situ* hybridization) using probes specific for the rDNA locus (Figure 6).

Recent studies have shown that the rDNA sequences are sufficient to form a functional, transcriptionally competent nucleolus (Grob *et al.*, 2014). However, several other gene loci have also been shown to be associated with nucleoli (Németh *et al.*, 2010; van Koningsbruggen *et al.*, 2010). These comprise several genes embedded within the heterochromatic shell around the nucleolus and are mostly, if not entirely, transcriptionally silent. An interesting aspect relating nucleolar structure with chromatin and gene expression has been demonstrated lately, as several publications in different model organisms have highlighted the importance of nucleolar chromatin for global genome regulation, such as the balance between eu- and heterochromatin and genomic stability (Paredes and Maggert, 2009; Ide *et al.*, 2010; Kobayashi, 2008).

In total, the diploid human genome contains ~400 rDNA repeat units of ~43 kb (~45 kb in mice) that are predominantly arranged in a head-to-tail fashion (Caburet *et al.*, 2005). The general organization of the individual rDNA repeat has been studied extensively. Only ~13–14 kb of each 43 kb unit code for rDNA and these are separated from each other by ~30 kb of intergenic sequences (‘intergenic spacer’; IGS). Many elements important for regulating rDNA transcription (promoter, enhancer, and terminator sequences) can be found within the IGS. So called ‘replication fork barriers’ (RFBs), situated between individual rDNA repeats, prevent the

Figure 6 NORs in metaphase and interphase cells. FISH analysis using probes against rDNA loci (stained in red) reveals the subcellular localization of NORs. (a) In metaphase cells, NORs (arrows) are localized to the p-arm of acrocentric chromosomes. (b) In interphase, NORs are localized to the FC in nucleoli.

collision of the replication and transcription machineries during S-phase (Brewer and Fangman, 1988; Gerber *et al.*, 1997; Wiesendanger *et al.*, 1994; Little *et al.*, 1993; Hernandez *et al.*, 1993). In addition, the IGS codes for a small, 150–250 nucleotide long, noncoding RNA, the so-called promoter RNA (pRNA), which is involved in epigenetic regulation of the rDNA locus (see below) (Mayer *et al.*, 2006; Santoro *et al.*, 2010).

Only about half of the rDNA repeats are actively transcribed during interphase while the rest are transcriptionally inactive, but all rDNA repeats reside within nucleoli (Sullivan *et al.*, 2001). These two classes of rDNA repeats differ from each other in their chromatin organization, epigenetic marks, and associated proteins (reviewed in Nemeth and Langst, 2011; McStay and Grummt, 2008). The active repeats carry euchromatic features, such as hypomethylated DNA and euchromatic histone modifications. In contrast, the inactive repeats are organized as heterochromatin, with hypermethylated DNA and repressive histone marks. This pattern is thought to be established by allelic inactivation early during development (Schlesinger *et al.*, 2009) and is actively maintained over the cell cycle.

Although the number of active rDNA copies varies depending on nutrient availability and the rate of cell proliferation, studies in different organisms have shown that even in rapidly dividing cells about half of those repeats remain transcriptionally silent (French *et al.*, 2003; Dammann *et al.*, 1993, 1995; Michel *et al.*, 2005). Maintenance of high numbers of rDNA repeats has been suggested to protect the rDNA locus from homologous recombination events that could reduce rDNA copy number below a putative critical threshold for viability. Extensive rDNA copy number variation exists within a single species. For example, Michel *et al.* (2005) found that *Saccharomyces cerevisiae* clonal variants with 50% fewer rDNA repeats show no significant short-term defects in mitosis, meiosis, or proliferation. Stable inactivation of excess, ‘backup’ rDNA repeats is consistent with a dosage compensation mechanism. Interestingly, dosage compensation appears to be a common theme in nature. For example, in plants a different form of dosage compensation has been described, involving one set of parental NORs being inactivated by a mechanism called ‘nucleolar dominance’ (reviewed in Preuss and Pikaard, 2007; McStay, 2006).

rRNA Transcription

About half of the cellular RNA synthesized in rapidly growing cells corresponds to rRNA transcribed by RNA Pol I (Warner, 1999). Misregulation of ribosome subunit biogenesis is associated with disease, including the so-called ribosomopathies and some cancers (for reviews see, e.g., Teng *et al.*, 2013; Narla and Ebert, 2010; Hannan *et al.*, 2013; Drygin *et al.*, 2010). It is generally assumed that rDNA expression is modulated in two distinct ways: either by adjusting the transcription rate of already active rDNA repeats, as demonstrated, for example, in response to growth factor signaling and nutrient availability, or by changing the number of active rDNA repeats, for example, during differentiation and development (reviewed in McStay and Grummt, 2008; Grummt, 2013).

Synthesis of rRNA is a highly efficient and regulated process that is still being studied intensively (for a recent in-depth review we refer to Goodfellow and Zomerdijs, 2013; Németh *et al.*, 2013). In brief, rRNA transcription, with the exception of the 5S rRNA, is mediated by multiple, densely packed transcription factories of RNA polymerase I. Distinct steps in the transcription process are (a) transcription initiation in the form of formation of the pre-initiation complex (PIC), (b) promoter escape, (c) elongation, and (d) termination, with each of these four steps reported to be subject to regulation mechanisms (Grummt, 2013; Goodfellow and Zomerdijs, 2013). Topological arrangements of the rDNA locus are believed to be important for high rRNA transcription efficiency. For example, the UBF-dimer is part of a specialised nucleosome structure on rDNA called the ‘enhanceosome’ (Stefanovsky *et al.*, 2006), which has been implicated in remodeling rDNA chromatin to a more ‘open’ state that is competent for recruitment of the PIC and transcription (Grob *et al.*, 2014; Sanij *et al.*, 2008). In addition, the formation of DNA-loops and clustering of TTF1 binding sites has been proposed to enhance reinitiation (Nemeth and Langst, 2011; Diermeier *et al.*, 2013; Denissov *et al.*, 2011).

Regulation of rDNA Expression

As described above, approximately half of the rDNA repeats are transcriptionally active, while the rest is silent. Regulation of rDNA expression can be dynamic; for example, by recruiting specific factors to rDNA to prevent binding of the RNA Pol I-associated transcription machinery. Additionally, direct chemical modification of either rDNA repeats, or rDNA-associated histones, can lead either to persistent activation, or silencing, of rDNA repeats that endures upon cell division.

Several key players in this latter, ‘epigenetic’ regulation of rDNA chromatin organization have been described in mammals. At the centre of this regulatory pathway is the rDNA binding protein TTF1 (transcription termination factor 1), which can either activate, or repress, rDNA transcription depending on the protein complex that is formed with TTF1 (reviewed in McStay and Grummt, 2008; Grummt and Langst, 2013). On the one side, TTF1 can recruit NoRC (nucleolar remodeling complex) by interacting with its subunit Tip5 (TTF1-interacting protein 5) (Strohner *et al.*, 2001; Santoro *et al.*, 2002). Another member of the NoRC complex is SNF2h, an ATPase required to shift nucleosomes along rDNA and prevent PIC formation at the promoter (Li *et al.*, 2006; Langst *et al.*, 1998). In addition to TTF1, TIP5 has been described to interact with several other proteins involved in repressing transcriptional activity, such as DNA methyltransferases (DNMT 1 and 3), histone deacetylases (HDAC1/2; Zhou *et al.*, 2002), and histone methyltransferases (HMTs). Importantly, NoRC requires the presence of pRNAs transcribed from the IGS within the hypomethylated (active) rDNA locus. However, pRNAs have also been described to exert transcription-repressive functions independently of TTF1 and NoRC by mediating rDNA *de novo* methylation (Schmitz *et al.*, 2010).

TTF1 has also been shown to interact with activating factors at the rDNA, in particular CSB (Cockayne syndrome protein B), a member of the SNQ/SNF2-like DNA-dependent ATPases

(Yuan *et al.*, 2007; Bradsher *et al.*, 2002). CSB is further associated with G9a, a euchromatic HMT involved in euchromatic histone methylation (Tachibana *et al.*, 2002). Other factors promoting an open chromatin structure include histone demethylases, such as PHF8, or the rDNA promoter binding, methylation-sensitive proteins MBD3 and GADD45a (Schmitz *et al.*, 2009; Feng *et al.*, 2010; Brown and Szyf, 2007). MBD3 and GADD45a binding to the rDNA promoter protects it against *de novo* methylation and actively favours its demethylated and active state.

Interchange of Nucleoli with Other Nuclear Bodies

Nucleoli are discrete, stable structures that can be isolated to high purity from mammalian cells, as shown by scanning electron microscopy in Figure 7. Nevertheless, the proteins within nucleoli are in constant flux with the surrounding environment. This includes proteins that in steady state may appear mainly nucleolar. This is illustrated in Figure 8 for the nucleolar marker protein fibrillarin by fluorescence microscopy using Fluorescence Loss In Photobleaching (FLIP). Importantly, proteins, which under normal conditions do not obviously have a nucleolar localization, may also transiently pass through the nucleolus, for example, the paraspeckle protein PSP1 (Fox *et al.*, 2002, 2005). Stable PSP1 association with the nucleolus can only be observed under specific cellular conditions, such as

Figure 7 SEM image of a purified HeLa cell nucleolus. Relatively pure nucleolar fractions can be extracted from a variety of cell types. In a typical protocol, cells are lysed and nuclei are separated from the cytoplasm by centrifugation. Purified nuclei are submitted to mild sonication to break them open while keeping nucleoli intact and separating them from the surrounding chromatin. Free nucleoli can be purified from other nuclear material by centrifugation through sucrose cushions. For a detailed protocol, see: http://www.lamondlab.com/newwebsite/Cellular_fractionation_protocols.php

following inhibition of RNA Pol II transcription. Therefore, the nucleolar proteome is, at least partially, shared with other subcellular compartments, especially the nucleoplasm and other nuclear bodies (Box – The Nucleolus and Other Nuclear Bodies).

Out of the plethora of nuclear bodies, the Cajal body (CB) is especially well known to be closely associated with the nucleolus. Their close spatial relationship was initially recognized by Santiago Ramon y Cajal, in 1903, who first described Cajal bodies (CBs) in human neurons and named them ‘nucleolar-associated body’ (Cajal, 1903). This liaison is highlighted by the fact that nucleoli and CBs share a common pool of proteins (reviewed by Machyna *et al.*, 2013). In addition, the CB marker coilin can be found under certain physiological conditions to be associated with, or even to accumulate within, nucleoli. For example, this has been shown in the nucleoli of the hibernating dormouse (Malatesta *et al.*, 1994a, b; Ochs *et al.*, 1994). Given this close spatial relationship, it is not surprising that nucleoli and CBs are also functionally linked, such as by their role in the biogenesis and assembly of RNP complexes (reviewed by Mao *et al.*, 2011), and in the cellular stress response (Boulon *et al.*, 2010). An intensively studied pathway involves the biogenesis of snoRNPs that are required for the processing of rRNA in the nucleolus. They have been shown to assemble and mature within the CB before being transported to the nucleolus (reviewed in Verheggen and Bertrand, 2012). Another example is the biogenesis of the spliceosome component U6 snRNP (reviewed in Machyna *et al.*, 2013; Stanek and Neugebauer, 2006; Patel and Bellini, 2008). After its transcription by RNA Pol III in the nucleoplasm, the U6 snRNA will pass through the nucleolus for its maturation before reaching the CB for its final assembly into the snRNP spliceosomal subunits.

Similar to nucleoli, CBs are dynamic nuclear bodies, whose number and size varies according to the metabolic activity of the cells (Ciocce and Lamond, 2005). Also, their structure changes in response to various types of stresses (Boulon *et al.*, 2010). For example, DNA damage by UV-treatment results in dispersal of CBs and in the appearance of coilin microfoci (Ciocce *et al.*, 2006). Other perturbations highlight the close relationship of CBs with the nucleolus. A prime example here is nucleolar cap formation upon transcriptional inhibition (see below). In addition, impairment of snRNP biogenesis at various stages has been shown to result in relocation of coilin into the nucleolus (reviewed in Boulon *et al.*, 2010). Therefore, both nucleoli and CBs have been described as stress sensors, or ‘hubs,’ for the cellular stress response (Boulon *et al.*, 2010; Emmott and Hiscox, 2009).

The Dynamic Nucleolus

As described in the preceding sections, the nucleolus plays an indispensable role in ribosome subunit biogenesis, which in turn is critical for cell growth, proliferation, and cellular function. As such, the structure and function of nucleoli are tightly coupled to cellular states and can rapidly respond to changing intracellular and extracellular conditions, such as stress, cell cycle stage, and nutrient availability. Here we seek to highlight only a few examples of nucleolar dynamics,

Figure 8 Nucleolar proteins are highly dynamic. (a, top) GFP-fibrillarin was photobleached in one nucleolus (arrow) and fluorescence intensities were measured in regions of interest (ROIs) in another nucleolus within the same cell (blue box) and a different cell (red box). The fluorescence intensity of GFP-fibrillarin decreases in unbleached nucleoli (blue box) and in the nucleoplasm, showing that photobleached GFP-fibrillarin rapidly exchanges with fluorescent GFP-fibrillarin during the timescale of the experiment. Photobleaching does not affect GFP-fibrillarin fluorescence in a neighboring cell (red box). (a, bottom) Photobleaching of GFP-H2B in the area indicated by the arrowhead does not significantly decrease the surrounding GFP-H2B intensity (measured in the green box). In contrast to GFP-fibrillarin, core chromatin components (such as GFP-H2B) are relatively static and do not exchange during the short timescale of the experiment. (b) Quantitation of the fluorescence intensities measured in the red, blue, and green boxes are shown. The photobleaching experiment was performed on a DeltaVision Core Restoration Microscope equipped with a Quantifiable Laser Module (Applied Precision).

including the nucleolar stress response and the assembly and disassembly of nucleoli during the cell division cycle.

Nucleolar Dynamics in Response to Transcriptional Inhibition and DNA Damage

Transcriptional inhibition and DNA damage caused by UV-damage are two well-known examples that result in changes in the protein composition of the nucleolus (Carmo-Fonseca *et al.*, 1992) and in nucleolar segregation (Al-Baker *et al.*, 2004; Govoni *et al.*, 1994), i.e., a separation of the nucleolar FC and DFC compartments, and relocalisation of nucleolar proteins

into nucleolar caps (Shav-Tal *et al.*, 2005; Carmo-Fonseca *et al.*, 1992; Figure 9(a); Movie 2).

Using combined EM and fluorescence microscopy, distinct types of nucleolar caps have been described in the case of inhibition of RNA Pol I dependent transcription, each harboring a distinct set of protein and RNA species (Shav-Tal *et al.*, 2005). It is interesting to note that multiple proteins that are normally not observed by microscopy to be accumulated in nucleoli are recruited to nucleolar caps. The list includes many proteins from other nuclear bodies, including reference markers such as coilin for CBs (Figure 9(b)), PSP1 for paraspeckles, and PML for PML bodies, all of which locate to distinct forms of nucleolar caps. (For more on nuclear bodies,

The Nucleolus and Other Nuclear Bodies

'Nuclear body' is an inclusive term used to collectively describe structures where specific sets of proteins, and often also nucleic acids, can be visualized within the nucleoplasm of a cell. The largest nuclear body is the star of this article, the nucleolus. Other well studied nuclear bodies include PML bodies, Cajal bodies (CBs), splicing speckles, and paraspeckles.

- CBs, previously called 'Coiled bodies,' are named in honor of their discoverer, the famous Spanish histologist Santiago Ramón y Cajal (Cajal, 1903). They are defined as foci enriched in the protein coilin. CBs are thought to function in the maturation of small nuclear ribonucleoproteins (snRNPs) and small nucleolar ribonucleoproteins (snoRNPs) (note that the maturation of at least one snRNP RNA, U6, also requires the nucleolus). CBs are often found in close proximity to the nucleolus with which they have a close relationship. In fact, Cajal first described CBs as 'Nucleolus Accessory Bodies.' This relationship with the nucleolus is illustrated by the presence of nucleolar proteins, such as fibrillarin, inside CBs and the propensity of CB proteins to relocate to the surface of the nucleolus, forming nucleolar 'caps,' in response to some forms of stress, for example, after transcription inhibition (see Figure 8). In rare cases, such as in hibernating dormouse hepatocytes, CBs are detected as defined bodies within the nucleolus (Malatesta *et al.*, 1994a,b).
Another type of nuclear body, Gems (Gemini of Coiled Bodies), had originally been described as foci containing the protein survival of motor neuron (SMN) (Liu and Dreyfuss, 1996). As their name implies, Gems are closely associated with CBs. In fact, in most cells CBs and Gems are undistinguishable. Interestingly, while one strain of HeLa cells was found to have distinct CBs and Gems, in another they overlapped completely (Matera and Frey, 1998). It may be better to consider that Gems are in fact a subtype of coilin-less CBs only found in certain cell types. The significance of this has not yet been understood.
- Promyelocytic leukemia (PML) bodies (Weis *et al.*, 1994), variously referred to either as Nuclear Domain 10 (ND10), PML oncogenic domains (PODs, a misleading name as they are not oncogenic), Kremer bodies, or nuclear dots. Most cells will contain between 10 and 20 PML bodies, each with a diameter in the 0.3–1 μm range. PML bodies tend to be found close to transcriptionally active DNA. They have been suggested to play a role in multiple processes, including transcriptional regulation (Zhong *et al.*, 2000), viral infection and the interferon response (Regad and Chelbi-Alix, 2001), apoptosis and senescence (Bischof *et al.*, 2002; Bernardi and Pandolfi, 2003), and tumor suppression (Gurrieri *et al.*, 2004). Many proteins in PML bodies — including PML — are SUMO-modified, and it has been suggested that SUMOylation, while not required for formation of PML-containing foci, may be essential to recruit other components of the bodies (Seeler and Dejean, 2001).
- Splicing speckles, or interchromatin granule clusters, are irregular nuclear structures of variable size and shape, each appearing as a rather loose grouping of small foci linked by fibrils, typically found in regions of the nucleoplasm with relatively low DNA density (Lamond and Spector, 2003). They contain pre-mRNA splicing factors as well as a subpopulation of RNA Pol II complexes and at least one specific poly(A)⁺ mRNA. Speckles are thought to function mainly as sites of storage or recycling of splicing factors. Thus, speckles increase in size when transcription is inhibited and splicing factors are inactive.
- Paraspeckles, as their name implies, are found in close proximity to splicing speckles (Fox *et al.*, 2002). Their function is as yet unclear, but they have been suggested to play a role in nuclear retention of large hyper A-to-I edited RNAs (Fox *et al.*, 2005). Most proteins that locate to paraspeckles have RNA binding activity, and paraspeckles contain a specific, long noncoding RNA molecule called NEAT1. Interestingly, paraspeckles were first identified as accumulations of PSPC1 (Fox *et al.*, 2002), a protein first identified in a nucleolar proteomics screen (Andersen *et al.*, 2002). PSPC1 accumulates in nucleoli if transcription is inhibited. It has subsequently become clear that most of the paraspeckle proteome transits constantly through the nucleolus. Because many paraspeckle proteins have diverse, mostly unrelated functions, it has been suggested that one of the primary roles of paraspeckles may be to sequester proteins involved in RNA metabolism to regulate their activities.

For as long as the existence of nuclear bodies has been recognized, researchers have debated about the link between their structure and function. Have proteins involved in the organization of nuclear bodies been selected during evolution as scaffolds improving the efficiency of cellular processes by locally concentrating the factors involved, or are the structures we perceive as nuclear bodies the indirect result of the local concentration/exclusion of activities? Maybe nuclear bodies are simply storage areas for excess nuclear proteins. Different explanations may apply to different forms of nuclear bodies. One thing appears certain, nuclear bodies are highly dynamic, and most, if not all, of their components can constantly shuttle in and out of the structures. There is also evidence that some component proteins are shared between different nuclear bodies and move between them in a specific order, demonstrating the existence of molecular sorting pathways in the nucleus akin to those seen in the cytoplasm. This is typified by the behavior of splicing snRNPs, which accumulate in CBs when they first enter the nucleus before relocating to splicing speckles (Sleeman and Lamond, 1999; Leung and Lamond, 2002). Another example is that of nucleolar caps discussed above and at more length in the main body of this article (Shav-Tal *et al.*, 2005).

To learn more about:

- CBs (Machyna *et al.*, 2013),
- PML bodies (Everett and Chelbi-Alix, 2007),
- splicing speckles (Spector and Lamond, 2011),
- paraspeckles (Nakagawa and Hirose, 2012; Fox and Lamond, 2010),
- or nuclear bodies in general (Mao *et al.*, 2011; Dundr, 2012; Caudron-Herger and Rippe, 2012; Sleeman and Trinkle-Mulcahy, 2014; Dundr and Misteli, 2010).

see 'Nuclear Bodies' Box and Movies 3–6). Since many of the nonnucleolar proteins seen to locate to caps have as a common feature RNA binding, it is likely that the massive changes observed upon transcription inhibition are a consequence of the constant RNA-dependent mobility of those factors. Thus, as their specific RNA targets become scarce, these proteins then accumulate at the nucleolar periphery, even if in normal cells the same proteins would be mainly detected outside of the

nucleolus. Nucleolar cap proteins may potentially bind to different RNA or protein targets depending on the nature of the nucleolar cap formed. Importantly, not all stresses have the same effect on the nucleolus and nuclear bodies, suggesting that the caps formed under different stress conditions may vary in protein composition or structure (see Table 1 in Boulon *et al.*, 2010). The phenomenon of nucleolar cap formation reflects the dynamic relationship of the nucleolus with other

Figure 9 The nucleolar response to stress. (a) In cells stressed by inducing transcriptional inhibition with actinomycin D, nucleolar proteins, such as fibrillarin and UBF, are relocated to nucleolar caps (arrows). (b) Transcriptional inhibition also causes proteins associated with other nuclear bodies, such as the Cajal body-protein coilin (arrowheads), to localise to nucleolar caps (arrows). Importantly, while localization of nucleolar proteins and nuclear body-associated proteins to caps is frequently observed in response to diverse stresses, not all stresses are associated with cap formation, and it is likely that the exact protein composition of the nucleolar cap depends on the specific type of stress (for review see Boisvert *et al.*, 2007). See Movie 2 for a time-lapse video showing the dynamic formation of nucleolar caps in response to transcriptional inhibition.

nuclear bodies or the nucleoplasm and the fact that the structure of nuclear bodies is highly dynamic and intimately linked to their function(s).

Nucleolar Signaling Networks in the Metabolic Stress Response

Given the high proportion of cellular energy spent in ribosome subunit biogenesis (Granneman and Tollervey, 2007), it is perhaps no surprise that nucleolar function and structure are connected to mitogenic signaling and intracellular energy status. One important mechanism that dynamically controls ribosome subunit biogenesis is the regulation of rRNA synthesis. Recent studies have elucidated several ways in which rRNA synthesis is controlled in response to cellular energy levels. These include epigenetic silencing of rDNA gene loci by recruitment of chromatin remodellers (Murayama *et al.*, 2008; Tanaka *et al.*, 2010) and modulation of RNA polymerase I activity (Chen *et al.*, 2013).

The main pathway involved in regulation of cell growth in relation to nutrient sensing is centered on the serine/threonine kinase mTOR, the mammalian homolog of yeast Target of Rapamycin (TOR). mTOR is a component of two complexes, mTORC1 and mTORC2 (Loewith *et al.*, 2002). Only mTORC1 appears to be directly involved in controlling ribosome subunit synthesis, among its diverse growth regulation related functions (Powers and Walter, 1999). It has been shown – primarily in yeast – that TORC1 integrates nutrient and energy levels, as well as growth factor signaling, and affects ribosome subunit synthesis by a variety of mechanisms. For example, TORC1 has been shown in mammals and yeast to regulate the transcription of both Pol I and Pol III dependent rRNA genes (Mahajan, 1994; Cardenas *et al.*, 1999). TORC1 binds to rDNA at promoters, recruits specific transcription factors to them in a nutrient dependent manner, and regulates rDNA chromatin structure (Tsang *et al.*, 2003, 2010; Li *et al.*, 2006). TORC1 also controls the speed of RNA Pol II dependent transcription, which in turn affects the levels of ribosomal protein mRNAs (Powers and Walter, 1999; Cardenas *et al.*, 1999; Hardwick *et al.*, 1999; Beck and Hall, 1999). Finally, besides the general enhancement of RNA Pol II dependent transcription, TORC1 specifically stimulates the translation of terminal oligopyrimidine (TOP) mRNAs, the class of mRNAs that code for ribosomal proteins. However, the exact mechanism by which this occurs is still unclear (Tang *et al.*, 2001; Pende *et al.*, 2004).

Another mechanism of energy homeostasis is the reduction of energy requirements during conditions of stress by arresting cell growth and proliferation. Two key regulators of cell growth and proliferation are the tumor suppressor proteins p53 (reviewed in Lohrum and Vousden, 1999) and p21^{Cif/Waf} (reviewed in Jung *et al.*, 2010), which are both maintained at low levels during active proliferation by targeted protein degradation mechanisms. In the event of cellular stress, the levels of these proteins are rapidly upregulated to arrest proliferation and growth, which can ultimately result in either cellular senescence, autophagy, or apoptosis. This is achieved quickly, at least in part, through suppression of their targeted degradation.

Like p53, levels of the nucleolar protein p14ARF are kept low under cell proliferative states and rapidly upregulated under stress conditions (reviewed in Sherr, 2000). Nucleoplasmic p14ARF can bind and inactivate the protein Hdm2, which is the E3 ligase that targets p53 for degradation, thus leading to stabilization of the p53 protein (reviewed in Vousden, 2002; Sherr, 2001). Recently, a novel p53-independent pathway has been discovered where p14ARF can stabilize levels of p21 by upregulation of the protein FMN2 (Yamada *et al.*, 2013; Vaartjes and Boom, 1987), which is also found in nucleoli. It has also been shown that the novel nucleolar protein ARHGAP11A accumulates in the nucleus upon DNA damage and subsequently binds and stabilizes an active form of p53 (Xu *et al.*, 2013). A common theme that emerges from these studies is that conditions of stress can result in nucleoplasmic accumulation of nucleolar proteins, which stabilize levels of p53 and lead to an arrest of cell growth and proliferation (Rubbi and Milner, 2003). In addition to the mTOR pathway described above, these pathways provide crucial links between cellular energy/stress states and ribosome subunit biogenesis.

Nucleolar Dynamics during the Cell Division Cycle

The nucleolus is dynamically disassembled and reassembled with each cell division (Dundr *et al.*, 2000). Nucleolar disassembly begins during the early stages of mitosis. Simultaneously, transcription of rDNA genes is halted (Weisenberger and Scheer, 1995; Klein and Grummt, 1999), perhaps to allow for chromatin condensation and segregation. As shown in Figures 10 and 11, nucleolar assembly and disassembly is ordered with respect to the tripartite compartments FC, DFC, and GC (Leung *et al.*, 2004). Among the first components to leave nucleoli are RNA Pol I-associated proteins in the FC, followed by proteins in the DFC, and then finally the GC. Reassembly begins during late telophase with recruitment of RNA Pol I-associated factors to rDNA loci and reinitiation of rDNA transcription (i.e., FC proteins), followed by recruitment of DFC and then GC proteins. Interestingly, specific RNA Pol I factors such as UBF remain localized to rDNA loci during the entire cell cycle (Leung *et al.*, 2004; Scheer and Rose, 1984; Roussel *et al.*, 1993). It has been suggested recently that these constitutively chromatin-bound RNA Pol I factors are important in nucleolar reassembly (Grob *et al.*, 2014).

Nucleoli and Viruses

There is a large body of reports that multiple viruses – including RNA and DNA viruses and retroviruses – interact with the nucleolus (for reviews, see Wang *et al.*, 2010; Salvetti and Greco, 2014; Ni *et al.*, 2012; Hiscox *et al.*, 2010; Hiscox, 2007). Many viral proteins localize, at least partially, to nucleoli, while nucleolar proteins are in other cases relocalized from the nucleolus to virus-induced complexes. Viruses also appear to target the nucleolus because it plays a role in several antiviral responses, of which the best known is the p53 pathway. Striking examples of virus–nucleolus interactions can be found among the herpes viruses, which, like most other DNA viruses,

Figure 10 Nucleoli are dynamically assembled and disassembled during the cell division cycle. During prophase/prometaphase, chromatin begins to condense (represented as thick line segments) and some FC proteins, such as RPA39, exit the nucleolus, while other FC components, such as UBF, remain constitutively bound to NORs during mitosis. Between prometaphase and metaphase, the remaining nucleolar architecture is disassembled and remains so until after anaphase. By mid-telophase, FC proteins are recruited back to NORs and the DFC begins to reassemble. The last compartment to reassemble is the GC, which does so during late telophase/early G1.

replicate in the nucleus. For example, herpes simplex 1 replication is associated with first swelling, then major disruption of the nucleolus, until it virtually ceases to exist and all the cellular chromatin is 'marginalized' at the nuclear periphery (Monier *et al.*, 2000; Sirtori and Bosisio-Bestetti, 1967). Similar phenotypes have been observed for other herpes viruses (Luo *et al.*, 2007; Wang *et al.*, 2006; White, 2007). Additionally, various herpes viruses have been shown to encode nucleolus targeting proteins (reviewed in Ni *et al.*, 2012). For example, gamma herpes viruses encode a protein, ORF57, which localizes to the nucleolus where it hijacks ribosome export pathways to export unspliced viral mRNAs (Boyne and Whitehouse, 2006, 2009). However, in most cases the functional significance of virus-nucleolus interactions is still unclear. Moreover, there does not appear to be a single unifying theme behind these interactions. Rather, it is likely that diverse viruses have independently seized opportunities to exploit interactions with nucleolar factors – as would be expected to occur for such a major cellular compartment over hundreds of millions of years of coevolution.

Proteomic Studies on Nucleolar Architecture, Function, and Dynamics

Nucleoli can be successfully purified from human cells using a combination of hypotonic lysis, sonication, and centrifugation in sucrose cushions (see Figure 7; a detailed purification

protocol is available at Relevant Website Section – Lamond Laboratory; an alternate method has also recently been described, see Liang *et al.*, 2012). These methods enable biochemical analysis of the molecular composition and structure of isolated nucleoli, and complement studies performed in cells, such as immunofluorescence microscopy. In recent years, advances in large-scale protein and nucleic acid sequencing have been used to characterize the nucleolar and nucleolar-associated proteins, RNA, and DNA under diverse cellular conditions (van Koningsbruggen *et al.*, 2010; Moore *et al.*, 2011; Boisvert and Lamond, 2010; Boisvert *et al.*, 2012).

Researchers have used mass spectrometry (MS) based identification and quantification to catalog the proteins from human cells that localize to nucleoli, or are otherwise co-purified with nucleoli. These are publicly available in the nucleolar protein database (see Relevant Website Section – NopDB). The nucleolar proteome is highly enriched in proteins associated with ribosome subunit biogenesis and RNA processing, as expected from the principal function of the nucleolus. Interestingly, the nucleolar proteome is also enriched in proteins associated with other biological processes, such as cell cycle and viral replication. These auxiliary functions are consistent with a multifunctional, or plurifunctional, view of the nucleolus (Pederson, 1998; Rubbi and Milner, 2003; Olson, 2004; Pederson and Tsai, 2009).

In addition to in-depth characterization of the protein constituents of the nucleolus, MS has been used to study dynamic changes to the nucleolar proteome under various stress

Figure 11 Immunofluorescence analysis of nucleolar disassembly and reassembly. Nucleolar compartments were visualized in asynchronous U2OS cells stained with anti-UBF (FC, green), anti-fibrillarin (DFC, red), and DAPI (DNA, blue), and transfected with a plasmid encoding mCherry-tagged B23 (GC, orange). Cells undergoing mitosis in this asynchronous population were selected for imaging and shown below. Scale bars are 10 μm .

conditions. Key to the success of this approach is accurate relative quantification of protein levels using stable isotope labeling of amino acids in cell culture (SILAC) (Ong *et al.*, 2002). MS-based proteomics has been used to examine nucleolar proteome dynamics upon transcriptional inhibition, viral infection, and DNA damage, revealing stress-specific, complex reorganization of the nucleolus during the stress response (Liang *et al.*, 2012; Westman *et al.*, 2010; Westman and Lamond, 2011; Kar *et al.*, 2011; Emmott *et al.*, 2010a,b; Lam *et al.*, 2010; Jarboui *et al.*, 2012).

In a related approach called ‘spatial proteomics,’ the relative distribution of proteins between different cellular compartments is measured. For example, the measurement of the cytoplasmic, nuclear and nucleolar distribution of proteins was used to characterize dynamic changes in protein localization following DNA damage (Boisvert and Lamond, 2010;

Boisvert *et al.*, 2010). A similar approach was used to measure compartment-specific turnover rates of over 8000 proteins in human cells and identified a subset of proteins that have nucleolar-specific turnover rates (Boisvert *et al.*, 2012; Ahmad *et al.*, 2012). These data highlight proteins that are present in cells in different functional pools and whose regulation is dependent on subcellular localization.

Conclusion

Nucleoli are striking nuclear organelles that are present in all eukaryotes and whose sole function was long thought to be to facilitate and accelerate rRNA synthesis, processing, and pre-ribosome subunit assembly by concentrating factors required for these processes in a single organelle. In the last few

decades, work by many laboratories has begun to expand our understanding of the role of the nucleolus in the cell. In this article, we have highlighted examples of additional roles for the nucleolus, such as a hiding place for signaling proteins that mediate the cellular response against stress, and for integrating cellular contextual signals, such as nutrient availability, to control rates of global gene expression. We anticipate that more mechanisms will be uncovered in the future that will link the nucleolus to other aspects of cell biology.

Methods

Unless otherwise specified, all microscopy images were acquired with a DeltaVision Core Restoration microscope mounted on an Olympus IX71 stand with a 60 × 1.42 or 1.40 NA oil immersion objective.

Acknowledgments

We thank our colleagues in the Lamond lab for advice and discussion, the Joost Zoomerdijk lab for the mCherry-CAST plasmid, Martin Kierans for help with electron microscopy, Markus Posch for help with super-resolution OMX microscopy, and Jonas Telorac (Max Planck Institute for Molecular Genetics) for performing the rDNA FISH. AIL is a Wellcome Trust Principal Research Fellow. This work was supported by grants to AIL from the Wellcome Trust (Grant#:083524/Z/07/Z, 097945/B/11/Z, 073980/Z/03/Z, 08136/Z/03/Z, and 0909444/Z/09/Z), the EU FP7 Prospects network (Grant#: HEALTH-F4-2008-201648) and EpiGeneSys network (Grant#: HEALTH-F4-2010-257082), and the BBSRC sLoLa (Grant#: BB/K003801/1).

Glossary

Autophagy The regulated destruction of organelles within a cell, either following damage or to recycle biomolecules.

Cell stress The damage which occurs to cell components from external or internal factors. Cells have mechanisms to detect stress, signaling pathways to relay this detection and processes to deal with the stress.

Ribosome biogenesis The process by which ribosomes are synthesized from their constituent parts, namely, the

association of ribosomal proteins and ribosomal RNAs. The process also requires multiple non-ribosomal components called ribosome biogenesis factors.

Translation The process of making proteins, which is carried out by the mature ribosome. The term translation is used due to the need to change the genetic code in the form of mRNA into a protein sequence.

Introduction

Ribosome stress is a broad term applied to interactions between the cellular stress response and elements of the ribosome. Ribosome stress encompasses nucleolar stress – nucleoli are after all where ribosomes are made – but also pertains to stress in the context of translation by the ribosome. Despite spatial separation between nucleolar pre-ribosomes and cytoplasmic ribosomes, there are similarities in their regulation in response to stress. Cellular stress comes in many forms, from damage of cell components to reduced levels of nutrients. Genetic aberrations are also a stress, which may lead to the altered expression of genes and potentially oncogenic consequences. Importantly, ribosome stress has to be considered a two-way interaction where nucleoli and ribosomes also create and detect stress.

The mechanical activity of the ribosome is one of the most energy consuming activities in the cell. In proliferating cells the proportion of energy consumed by translation is second to only one other activity – the energy demanded for the synthesis of ribosomes themselves. This places ribosomes at the forefront of cellular energy management as their suppression (either at synthesis, during translation or both) will rapidly reduce energy expenditure. This article primarily follows the life of the mammalian ribosome (with other organisms referenced appropriately), from synthesis in nucleoli, function in the cytoplasm and finally considers ribosome degradation, showing that ribosomes are linked to stress sensing and signaling at each stage ([Figure 1](#)).

Ribosome Birth in the Nucleolus

Ribosomes consist of two subunits assembled from their constituent parts – 4 ribosomal RNAs (rRNAs) and 80 ribosomal proteins (RPs). Ribosomes are made in the nucleolus, a protein-rich subnuclear compartment which forms upon transcribed rDNA. RNA polymerase I transcribes rDNA, making an rRNA precursor that contributes to both subunits. This ensures stoichiometric synthesis of 40S and 60S subunits, but requires the activity of hundreds of auxiliary ribosome

biogenesis (RiBi) factors to cleave and modify the rRNA. As well as RNA polymerase I, ribosome biogenesis requires RNA polymerase II for synthesis of RP and RiBi protein mRNAs and RNA polymerase III for 5S rRNA and snoRNAs (a form of RiBi consisting of RNA). This makes ribosome biogenesis the ideal process to sense transcriptional health. When we also consider that the production of RPs and RiBis requires production of protein, and that nucleoli contain DNA, the nucleolus is an obvious choice to detect cell damaging stress.

Stress Detection by the Nucleolus – p53 Activation

Early studies with mouse models provided evidence for a p53 checkpoint in ribosome biogenesis, with liver-specific RPS6 knock-down resulting in cell cycle arrest ([Volarević et al., 2000](#)). Acting as a stress-responsive hub, the transcription factor p53 activates genes involved in cell cycle regulation, apoptosis, DNA repair and senescence. P53 is regulated primarily by one of its target gene products, human double minute 2 (HDM2, called MDM2 in mouse). HDM2 is an E3 ubiquitin ligase that poly-ubiquitinylates its targets, including p53. This auto-regulatory feedback loop occurs via two mechanisms: 1) inhibition of the p53 transactivation domain and 2) decreased p53 stability through ubiquitinylation and proteasomal degradation (reviewed by [Zhang and Lu, 2009](#)).

Further evidence of a link between ribosome biogenesis and p53 was displayed by dominant negative mutants of the RiBi Bop1, which resulted in both inhibition of ribosome biogenesis and p53-dependent cell cycle arrest ([Pestov et al., 2001](#)). This was supplemented by the finding that p53 activation requires nucleolar disruption caused by a multitude of stresses ([Rubbi and Milner, 2003](#)). Importantly, both 40S and 60S ribosome subunit maturation pathways can signal stress to p53 independently, as evidenced by superinduction following perturbation of both pathways ([Fumagalli et al., 2012](#)). It is not surprising that tight and sensitive surveillance is implemented due to the necessity for ribosome function within the cell.

Ribosomal proteins

Nucleolar stress releases RPs into the nucleoplasm where a subset can interact with HDM2 to abrogate p53

Figure 1 The life of the ribosome and its links to stress. Birth: ribosomes are born in the nucleolus, where the major rRNA precursor is synthesized and assembled with RPs. A further rRNA is imported from the nucleoplasm. Two subunits are synthesized by independent pathways, releasing mature 40S and 60S subunits into the cytoplasm to begin their life as ribosomes. Nucleoli are capable of both sensing stress and also responding to stress signaling. Life: Translating ribosomes are regulated by stress signaling during initiation and elongation, but also serve an important role in surveillance of mRNA and protein quality. Death: ribosomes, or their precursors, have to be degraded if they are synthesized with faults or gain aberrations during their life. These defects are sensed and dealt with by different degradation mechanisms – pre-ribosome degradation is driven by nucleases, as is mature 40S subunit degradation. Whereas mature 60S subunit degradation is driven by the ubiquitin/proteasome system. Stress signaling can also promote degradation of ribosomes not harboring defects via ribophagy.

ubiquitinylation and degradation. The first evidence that RPs participate in the regulation of HDM2 came from the report of the association of RPL5 with HDM2 in a 5S rRNA-RPL5-HDM2-p53 complex (Marechal *et al.*, 1994). Subsequently, it was shown that upon nucleotoxic stress or serum starvation, RPL5, RPL11, and RPL23 can bind to HDM2 leading to the accumulation and activation of p53. Since then similar negative effects upon HDM2 have been found for a total of 14 RPs, summarized in Table 1.

With 14 of the 80 RPs binding HDM2 there is high redundancy in the system. Interestingly, these RPs are partially clustered within the ribosome: near the 5S rRNA and exit channel in 60S subunits and either side of the mRNA decoding center in the 40S subunit (Figure 2), but are required throughout the different stages of ribosome biogenesis (Table 1). Redundancy may be explained by different binding sites on HDM2 and mechanisms of regulation. Domain mutation experiments have revealed that RPL5, RPL11 and RPL23 all bind the central domain of HDM2 in a different fashion (Dai *et al.*, 2004). Similarly, the ability to inhibit HDM2's ubiquitin ligase activity varies across these RPs; over-expression of RPL11 fails to suppress p53 poly-ubiquitinylation to the same extent as RPL5 or RPL23 (Dai *et al.*, 2006). Moreover, although all are capable of stabilizing p53 via HDM2, over-expression of RPL37, RPS15 or RPS20 led to the

Table 1 Stress detection by ribosomal proteins

Protein	Subunit	Biogenesis involvement	P53/HDM2 dependent
RPL5	60S	Late	Y
RPL6	60S	–	Y
RPL11	60S	Late	Y
RPL23	60S	–	Y
RPL26	60S	Early	Partial
RPL37	60S	–	Y
RPS3	40S	Early	Y
RPS6	40S	Early	Partial
RPS7	40S	Early	Y
RPS9	40S	Early	N
RPS14	40S	Early	Y
RPS15	40S	Late	Y
RPS20	40S	Late	Y
RPS25	40S	Late	Y
RPS26	40S	Late	Y
RPS27	40S	Early	Y

Note: Human ribosomal protein names are given for those with signaling capabilities. These are grouped by subunit. The role of each protein in ribosome biogenesis of their respective subunits is given, denoted as either early or late stage. The dependence of the RPs on p53/HDM2 for signaling is indicated (Y=yes; N=no).

Figure 2 The location of HDM2 binding RPs in the ribosome. The human 80S ribosome is represented, with the two subunits shown individually from two opposite perspectives (Anger *et al.*, 2013). Ribosomal proteins highlighted in yellow on both subunits are able to bind HDM2 when not incorporated into the mature ribosome. These are clustered in the 60S subunit around the 5S rRNA and nascent peptide exit channel, and also in two areas the 40S subunit either side of the mRNA decoding center in the head and body.

induction of different p53 target genes, suggesting that the role of each RP is different (Daftuar *et al.*, 2013).

RPL5 and RPL11 have been identified as the master ribosomal regulators of HDM2/p53. Knockdown of either protein failed to activate p53 upon ribosome stress (Dai *et al.*, 2004; Jin *et al.*, 2004). It is possible that RPs act cooperatively upon HDM2, which has been demonstrated for RPL5 and RPL11 (Horn and Vousden, 2008). This may allow integration of defects at different stages of ribosome biogenesis (Table 1). It is also possible that redundancy may compensate for RP misregulation. We also have to consider the cumulative effect of these RP-HDM2 interactions – interestingly, under normal conditions RP expression may be restrained so that the RP-HDM2 response is prevented (Lam *et al.*, 2007). Upon stress, increased RPs in the nucleoplasm (either released from the nucleolus or aberrantly over-synthesized RPs imported from cytoplasm) can tip the balance and trigger the RP-HDM2 response. The RP-HDM2 pathway is summarized in Figure 3.

Nucleolar RNAs

RPs are not alone in signaling to p53; ribosomal RNAs also signal to HDM2. The 5S rRNA is involved in a pre-ribosomal complex together with RPL5 and RPL11, and is directly linked to HDM2 inhibition (Marechal *et al.*, 1994; Donati *et al.*, 2013). The 5S rRNA is critical within this complex and essential for p53 stabilization (Sloan *et al.*, 2013a). The MDM2

homolog MDMX, which heterodimerises with and enhances MDM2-mediated ubiquitinylation, can also be targeted by the 5S rRNA, leading to its rapid destabilization (Li and Gu, 2011). Furthermore, noncoding RNAs transcribed by RNA polymerase II from intergenic regions of rDNA have been shown to act as ‘sponges’ for factors containing a nucleolar detention signal (NoDS), including HDM2 (Audas *et al.*, 2012).

RiBi factors

RiBi factors respond to nucleolar stress and activate p53. Nucleolar multifunctional protein nucleophosmin (NPM), which is involved in the shuttling of factors for ribosome biogenesis, has a complex relationship with HDM2. Following stress, NPM relocates to the nucleoplasm and binds to HDM2 causing p53 activation (Kurki *et al.*, 2004; Itahana *et al.*, 2003). NPM can also enhance p53 target gene transactivation activity under stress conditions (Drygin *et al.*, 2009). However, in the absence of stress NPM promotes HDM2 activity by binding and sequestering the HDM2-suppressor p14^{ARF} within the nucleolus (Korgaonkar *et al.*, 2005; Colombo *et al.*, 2005).

P53-Independent Ribosome Stress

The importance of p53 in the response to ribosome stress is clear, but ribosome biogenesis is also monitored independently of p53. The yeast *Saccharomyces cerevisiae* lacks a p53

Figure 3 HDM2 suppression by the nucleolus during stress. Under normal conditions nucleoli synthesize ribosomes from their precursors. Simultaneously the HDM2/p53 axis suppresses p53, and other HDM2 targets via the ubiquitin/proteasome system. Upon stress, the nucleolus can become physically disrupted, correlating with reduced ribosome synthesis and alterations in the nucleolar proteome. Release of factors from the nucleolus can suppress HDM2 binding to its targets, allowing accumulation of transcription factors such as p53, and induction of a stress response.

homolog, but ribosome stress induced by defective ribosome biogenesis is able to disrupt the cell cycle (Bernstein *et al.*, 2007). Similarly, in *Drosophila melanogaster* where p53 has not been shown to participate in cell cycle regulation, the Minute phenotypes caused by RP haploinsufficiency are characterized by reduced proliferation linked to cell cycle regulation. In mammalian cells, somatic mutations and inactivation of p53 is the most common form of transformation occurring in cancers. As such, HeLa cells, bearing a wild-type p53 inactivated by the human papillomavirus, respond to nucleolar stress with an arrest in cell cycle and/or apoptosis (Lindström and Nistér, 2010). Also, in RP mutant mouse models, not all phenotypes are explained by p53 activation (Terzian and Box, 2013), although the ultimate test of this would be RP mutation in the context of a p53 null background.

The first confirmation in mammalian cells of a p53-independent response to ribosome stress came from the treatment of p53 null cells with actinomycin D. Inhibition of rRNA synthesis causes inhibition of HDM2 by RPL11, followed by stabilization of another HDM2 target: the transcription factor and cell cycle regulator E2F1 (Donati *et al.*, 2011). The E2F1 protein controls cell cycle progression from G1 to S phase via modulation of transcriptional targets. In addition, defects in ribosome biogenesis by RNA polymerase I inhibition or RP deficiency (RPS19, RPS6, RPL7a knock downs) decrease the expression of the proto-oncogene kinase PIM1, leading to cell cycle arrest (Iadevaia *et al.*, 2010). Upon ribosome stress, decreased PIM1 expression relieves the inhibition and degradation of cell cycle regulator p27^{Kip1}.

RPL11 also has further HDM2-independent effects, acting via the regulation of the oncogene c-Myc. C-Myc is a transcription factor involved in driving proliferation, cell growth, differentiation and stem cell renewal. RPL11 was shown to compete for binding to c-Myc transcriptional targets with its activator TRRAP (Dai *et al.*, 2007). In addition to inhibiting transcription of c-Myc targets, RPL11 can also interact with the

3'UTR of c-MYC mRNA and mediate a microRNA repression of c-Myc translation under stress (Challagundla *et al.*, 2011).

Nucleolar Signaling During Stress

The severity of stress signaling that can emanate from the nucleolus is testament to the requirement for fidelity in ribosome biogenesis. However, as well as being a cause of stress, cells use the nucleolus as part of the response to stress, mediated by dynamic localization of nucleolar proteins and multiple stress signaling pathways.

Nucleolar proteome dynamics

Mass spectrometry has proved an invaluable tool for the identification of over 700 proteins that reside in the nucleolus of cells. Importantly, localization of many of these proteins is dynamic following stress. Under normal conditions nucleoli are organized into sub-regions, which are disrupted following stress, and coupled to proteins leaving or entering the nucleolus (Andersen *et al.*, 2005). These protein dynamics signal physical nucleolar disruption to initiate a stress response. As discussed above, the exodus of RPs from the nucleolus to the nucleoplasm exemplifies these dynamics (Figure 3).

The classic example of a dynamic nucleolar protein is the tumor suppressor p14^{ARF}. P14^{ARF} promotes the accumulation of p53 and suppresses proliferation by promoting degradation of the RiBi NPM (Pomerantz *et al.*, 1998; Itahana *et al.*, 2003). Under normal conditions p14^{ARF} is an unstable protein which resides in the nucleolus (Rodway *et al.*, 2004). Activation of p14^{ARF} results in a physical interaction with HDM2, with subsequent localization apparently dependent upon the dose of p14^{ARF} but eliciting the same activation of p53. Low level induction localizes a fraction of p14^{ARF} to the nucleoplasm, which retains HDM2 in the nucleus but is subsequently degraded (Llanos *et al.*, 2001), whereas high levels of p14^{ARF}

cause nucleolar sequestration of HDM2 (Weber *et al.*, 1999; Tao and Levine, 1999).

Another example is the localization of the nucleolar protein SENP3 into the nucleoplasm following UV irradiation (Moore *et al.*, 2011). SENP3 functions as a deSUMOylation protease, which has been implicated in promoting the nucleolar localization of a 60S biogenesis complex, among other targets (Finkbeiner *et al.*, 2011). Nucleolar localization of this SENP3-regulated complex is lost with very similar kinetics to SENP3, suggesting that deSUMOylation promotes its nucleolar localization (Moore *et al.*, 2011). Interestingly, SENP3 also plays a part in the p14^{ARF} stress response, being targeted for degradation by a mechanism initiated by p14^{ARF}, and involving association with NPM (Kuo *et al.*, 2008). SENP3 degradation subsequently enhances overall SUMOylation levels, which allows p14^{ARF} to induce cell cycle arrest independent of p53.

Kinase signaling in the nucleolus

RNA polymerase I requires association with specialized transcription factors to synthesize rRNA. Suppression of ribosome biogenesis by targeting transcription ensures the maximal energy saving to the cell during stress. It is for this reason that a number of stress-responsive pathways directly target RNA polymerase I via its transcription initiation factor TIF-IA (Figure 4).

The c-Jun N-terminal kinases (JNKs) are ubiquitously expressed stress-activated protein kinases responsive to cell damage, managing the decision between cell survival and apoptosis. For example, the JNK pathway can promote p14^{ARF} nucleoplasmic relocation following genotoxic stress, to promote activation of p53 (Yogev *et al.*, 2008). The JNKs also modulate

ribosome biogenesis, with JNK2 directly phosphorylating TIF-IA in response to stress (Mayer *et al.*, 2005); phosphorylation of Thr²⁰⁰ impairs transcription machinery assembly, reducing rRNA synthesis. Phosphorylation by JNK2 also causes loss of nucleolar TIF-IA, which accumulates in the nucleoplasm, further perturbing rRNA synthesis (Mayer *et al.*, 2005).

The AMP-activated protein kinase (AMPK) senses energy availability via allosteric binding of ATP and ADP/AMP according to their intracellular ratio. Decreased ATP is indicative of reduced cellular energy production or overactive energy expenditure. AMPK promotes ATP production via phosphorylation of metabolic enzymes but also reduces ATP use, in part via the nucleolar stress response. Similar to JNK2, AMPK phosphorylates TIF-IA, disrupting interactions required for transcription initiation (Hoppe *et al.*, 2009). However, phosphorylation occurs at a different residue (Ser⁶³⁵) and has not been reported to affect TIF-IA localization.

The mammalian target of rapamycin (mTOR) protein forms two distinct complexes able to influence cell fate via kinase activity. The mTORC1 complex maintains phosphorylation of its targets when conditions are favorable for cell growth and proliferation. Upon stress mTORC1 activity is reduced, resulting in target hypo-phosphorylation. The physiological outcome of this phosphorylation switch is a reduction in energy expenditure. Suppression of mTORC1 by rapamycin modulates phosphorylation of TIF-IA, impairing the interaction with RNA polymerase I and causing localization to the cytoplasm (Mayer *et al.*, 2004). mTORC1 has roles in ribosome biogenesis beyond TIF-IA. mTORC1 nucleolar localization also promotes rRNA maturation, an effect which is lost following rapamycin-mediated inhibition of the kinase (Iadevaia *et al.*, 2012). Furthermore, S6K (a downstream target of mTORC1) is required for

Figure 4 Stress signaling to RNA polymerase I. Three transcription factors of RNA polymerase I are subject to regulation by posttranslational modification following stress. TIF-IA is phosphorylated on multiple residues by stress signaling kinase pathways. Phosphorylation results in suppression of rRNA synthesis via disruption of the RNA polymerase I initiation complex. SIRT7 promotes rRNA synthesis performing the deacetylation of PAF53 in a constitutive cycle of acetylation required for transcription. In response to stress SIRT7 nucleolar localization is lost, disrupting this acetylation cycle. SIRT1 suppresses rRNA synthesis via reduced RNA polymerase I initiation through deacetylation of TAF₆₈, and also via epigenetic silencing of rDNA. This responds to NAD⁺ availability, which is increased by reduction in cellular energy levels. We also note that NAD⁺ may be locally increased by NMNAT in the nucleolus and that the SIRT1 allosteric activator AROS is a RiBi which has an increased effect on SIRT1 during stress. P=phosphorylation; A=acetylation. Dashed line indicates an indirect mechanism.

optimal transcription of over 100 RiBi mRNAs in a mouse model of nutrient stress (Chauvin *et al.*, 2014).

Nucleolar sirtuins

SIRT1 is an important factor in managing stress, in part via modulation of ribosome biogenesis. SIRT1 activity is metabolically responsive due to dependence upon NAD^+ as a cofactor. NAD^+ levels increase during nutrient stress, resulting in an increase in SIRT1 activity that enhances mitochondria biogenesis, promoting energy generation (Canto *et al.*, 2009; Rodgers *et al.*, 2005). Supplementary to this, SIRT1 also regulates rDNA epigenetic availability under nutrient stress, acting in a suppressor complex with the methyl-transferase SUV39H1 to reduce rRNA transcription when NAD^+ levels are high (Murayama *et al.*, 2008). SIRT1 also reverses acetylation of the transcription factor component TAF₆₈, reducing rDNA transcription and suppressing ribosome biogenesis (Muth *et al.*, 2001). Active regulator of SIRT1 (AROS) is an allosteric activator of SIRT1, with enhanced activity towards SIRT1 following stress (Kim *et al.*, 2007; Knight *et al.*, 2013a). Interestingly, AROS is also a RiBi required for 40S biogenesis (Knight *et al.*, 2013b), presenting the possibility that SIRT1 activity can be modulated following perturbations in ribosome biogenesis via signaling from AROS.

In contrast to SIRT1, SIRT7 promotes ribosome biogenesis, acting directly upon the transcription machinery. SIRT7 participates in an acetylation/deacetylation cycle of the RNA polymerase I recruitment factor PAF53, with deacetylation promoting rDNA binding (Chen *et al.*, 2013). High SIRT7 expression correlates with proliferation, likely via SIRT7-driven rRNA production (Ford *et al.*, 2006). The nucleolar localization of SIRT7 is dependent upon the presence of rRNA, with reduced rRNA synthesis causing SIRT7 to localize to the nucleoplasm (Chen *et al.*, 2013). This allows continued acetylation of PAF53 to suppress rRNA transcription. Together this suggests opposing roles for SIRT1 and SIRT7, both of which are responsive to NAD^+ . Epigenetic suppression of rDNA by SIRT1 would presumably negate any potential effects of SIRT7, which requires access to rRNA to elicit its function. Interestingly, the NAD^+ synthesis enzyme NMNAT localizes to nucleoli and leads to rRNA suppression, consistent with the role of SIRT1 (Song *et al.*, 2013). However, it is possible that both sirtuins are equally responsive – SIRT1 suppresses rDNA under conditions of nutrient stress, whereas SIRT7 is only nucleolar in the absence of stress – suggesting a resolution explained by stress exposure. The role of sirtuins in signaling to RNA polymerase I is summarized in Figure 4.

The Busy Life of the Ribosome

The primary function of the mature ribosome is translation, which like all jobs is highly regulated. This is carried out by the ribosome-associating translation factors; however, the activity of ribosomes themselves should not be overlooked. The capabilities of the ribosome that are defined during their biogenesis are essential for modulation of both global and specific protein expression. This is especially evident following stress. Adding to their busy workload further is an important role for ribosomes in quality control of both proteins and mRNAs.

Stress Signaling to the Ribosome

Cap-dependent translation

mRNAs are modified by the addition of methylated guanine to their 5' ends, creating the m⁷G cap. These caps are bound by the cap-binding protein eIF4E, which in turn binds a scaffold protein eIF4G and an RNA helicase eIF4A. This complex (called eIF4F) recruits 40S subunits to mRNA via eIF4G's association with further initiation factors, notably the multimeric eIF3 complex in a process termed cap-dependent initiation. Each physical interaction requires two parties; the 40S subunit has coevolved with the cap-dependent initiation factors to facilitate recruitment. In yeast, the 40S uses its rRNA and RPS0A (mammalian RPSA) to bind eIF3 (Valášek *et al.*, 2003).

EIF4E binding-proteins (4EBPs) are important regulators of cap-dependent initiation. In their hypo-phosphorylated state the 4EBPs compete with eIF4G for association with eIF4E. Interaction between 4EBPs or eIF4G with eIF4E is mutually exclusive such that the 4EBPs disrupts the eIF4F complex, decreasing 40S recruitment to mRNA and therefore the global rate of translation. Nutrient deprivation, hypoxia, and double stranded DNA lesions lead to suppression of mTORC1 activity, hypo-phosphorylation of the 4EBPs and diminished cap-dependent translation – see Figure 5 (reviewed by Spriggs *et al.*, 2010). Heat shock also suppresses cap-dependent translation in part via mTORC1 but also via the sequestration of eIF4G to stress granules.

To allow control by cap-dependent initiation the ribosome must be a poor initiator without assistance from eIF4F – the quantity of 40S subunits and mRNAs within the cell is such that the two will interact, yet the ribosome does not initiate on the majority of mRNAs. However, cap-independent initiation is possible on a subset of mRNAs, which contain an internal ribosome entry site (IRES) (Jang *et al.*, 1988). IRESs are structured RNA sequences able to initiate translation of their message without requirement for all of the canonical initiation factors and may be present in up to 10% of human mRNAs (Johannes *et al.*, 1999; Mitchell *et al.*, 2005). For all IRESs the need for cap-binding by eIF4E is removed, allowing expression when cap-dependent translation is suppressed, such as during stress.

40S subunits are active in recruitment of IRES containing messages since suppression of 40S subunit abundance results in reduced IRES initiation, beyond the suppression of general translation (Huang *et al.*, 2012). Furthermore, the 40S protein RPS25 is required for IRES initiation as 40S subunits lacking the protein are unable to bind IRES mRNAs (Landry *et al.*, 2009). The effect may extend to overall ribosome integrity as two ribosome biogenesis factors involved in rRNA modification – dyskerin and fibrillarin – are each required for efficient initiation from IRESs (Yoon *et al.*, 2006; Marcel *et al.*, 2013). These examples illustrate the reduced translational repertoires of aberrant ribosomes that have escaped nucleolar surveillance, an effect which will be most severe when attempting to respond to stress (Figure 5).

Regulation of elongation

The energy used in translation is predominantly consumed during elongation – 2 molecules of GTP are hydrolyzed for each amino acid added to the peptide chain. Regulation can occur during elongation via phosphorylation of eEF2, one of these

Figure 5 Stress signaling to the translating ribosome. Translation is suppressed following stress via regulation of initiation and elongation. mTORC1 promotes cap-dependent translation by suppressive phosphorylation of 4EBPs. Under stress this activity is reduced, suppressing translation initiating from the mRNA cap. mTORC1 suppression also results in phosphorylation of eEF2, which suppresses elongation by the ribosome. Likewise, AMPK also promotes eEF2 phosphorylation following the detection of stress. The ability of ribosomes to initiate upon internal ribosome entry sites (IRESs) is dependent upon fully competent 40S subunits being synthesized, including correct incorporation of RPS25 and modification of rRNAs by dyskerin (ψ) and fibrillarin (M). P=phosphorylation. Dashed lines indicate an indirect mechanism.

GTPases. The ribosome requires eEF2 to fuel movement along a message, expelling the used tRNA and allowing decoding of the next codon. However, the ribosome senses a single phosphorylation at Thr⁵⁶, which occludes eEF2 from entering the ribosome. This phosphorylation is carried out by eEF2K, which is activated following stress to reduce eEF2 activity. For example, the mTORC1 pathway induces eEF2 phosphorylation via S6K/eEF2K following nutrient deprivation and hypoxia (Wang *et al.*, 2001). Similarly, reduced ATP availability is sensed by AMPK, which signals to eEF2K to conserve energy expenditure by suppressing elongation (Horman *et al.*, 2002). In both cases occlusion of phosphorylated eEF2 is essential for translational suppression (Figure 5). Interestingly the regulation of elongation has strong parallels with the regulation of rRNA transcription, sharing two of the same modulating kinases. Thus, activation of AMPK and suppression of mTORC1 has common effects upon ribosome biogenesis in the nucleolus and cytoplasmic ribosome function.

Stress Detection by the Ribosome

Ensuring the integrity of the proteome is essential for overall cell function. Protein fidelity is promoted by chaperones, which assist protein folding, and by mechanisms to degrade faulty proteins. Translation by the ribosome acts as the perfect place for quality control assessment for both nascent mRNA

and proteins. These functions are split between the 40S (mRNA) and 60S (protein) subunits.

Protein quality control

Chaperones promote correct protein folding and are required under non-stressed conditions but also following proteotoxic stress – stress that effects protein integrity such as heat or chemical insult (Albanèse *et al.*, 2006). Peptides are synthesized deep within the ribosome and subsequently exit via a channel within the 60S subunit, protecting the peptides until they exit. The length of peptide protected is around 40 amino acids. Chaperones have long been known to associate with the nascent peptide emerging from the translating ribosome, which is believed to facilitate their folding. Following proteotoxic stress from heat or chemicals, ribosomes globally stall upon messages within the first 50–65 codons, coinciding with the emergence of peptides from the exit channel (Liu *et al.*, 2013; Shalgi *et al.*, 2013). This stalling correlates with reduced chaperone association with ribosomes, indicating that ribosomes sense the availability of chaperones and pause to allow proteotoxic stress to be combatted (Figure 6(a)).

Stalling of ribosomes has also been linked to the ubiquitinylation and degradation of aberrant nascent peptides in yeast. A ribosome quality control (RQC complex) comprising of Ltn1, Rqc1, Tae2, and Cdc48 associates with stalled ribosomes (Figure 6(b)), using Cdc48 and Ltn1 to extract and ubiquitinylate the aberrant nascent chain (Brandman *et al.*, 2012).

Figure 6 Ribosomes as a platform for quality control. (a) Chaperones are required for elongation after emergence of a peptide from the ribosome exit channel. In the absence of chaperones, such as during proteotoxic stress, ribosomes stall as the nascent peptide exits. This can also be interpreted as the binding of chaperones to nascent chains signaling to the ribosomes to allow elongation. (b) Ribosome stalling drives recognition and degradation of defective peptides. Protein defects can stall ribosome elongation, signaling to the ribosome quality control (RQC) complex to extract and ubiquitinate the peptide for proteasomal degradation. This complex can also enhance chaperone production via Hsf1. The RQC complex directly interacts with the 60S ribosomal subunit to elicit these functions. (c) Defective mRNAs stop ribosome elongation and are degraded by nucleases. mRNAs harboring an aberration require termination factors to halt translation upstream of the ribosome. Cleavage of the message occurs at the opposite side of the ribosome, suggesting that the ribosome acts as a platform for recruitment of nucleases.

Interestingly this requires the direct association of the RQC complex with the 60S subunit, a process which initiates prior to dissociation of the 80S ribosome but requires dissociation to complete (Defenuouillère *et al.*, 2013; Shao *et al.*, 2013). Of further note is the signaling capacity of the RQC complex, which uses Tae2 to up-regulate stress response chaperones via the transcription factor Hsf1 (Brandman *et al.*, 2012). This signal comes directly from stalled 60S subunits. The system has been characterized in yeast, and is genetically conserved in mammals, where the mammalian Ltn1 homolog is mutated in a murine model of neurodegeneration linked to defective protein quality control (Bengtson and Joazeiro, 2010).

mRNA quality control

mRNA surveillance has been categorized according to 3 different types of mRNA aberration and the degradation systems employed to eradicate them: mRNAs with an early stop codon (nonsense mediated decay), those lacking a stop codon (nonstop decay) and those whose structure inhibits elongation by the ribosome (no-go decay) (reviewed by Shoemaker and Green, 2012). For the latter two, poor quality is signaled by

stalling of the ribosome, either due to mRNA structure or to the synthesis of a stall-inducing basic polylysine tract from the polyA tail. An early stop codon can be recognized by the presence of an exon junction complex downstream of the terminating stop codon, or the distance between the stop codon and the 3'UTR.

After recognition of aberrant mRNA, endo- and exonucleases are recruited to cleave the message and degrade each fragment in both directions, efficiently removing the capacity to translate the mRNA (Eberle *et al.*, 2009; Gatfield and Izaurralde, 2004). Termination factor binding is required to initiate degradation, but mRNA cleavage occurs at the opposite side of the ribosome (Shoemaker *et al.*, 2010; Becker *et al.*, 2011). This has led to a theoretical role for the ribosome as a scaffold for recruitment of the degradation machinery (Figure 6(c)).

The End of the Line – Ribosome Degradation

Ribosome synthesis is subject to strict surveillance to ensure production of optimally functional ribosomes. Nevertheless, this process is error prone necessitating the degradation of aberrant ribosomal precursors. Ribosome surveillance does not stop in the nucleus, with proof-reading occurring in the cytoplasm and mechanisms present to eliminate aberrant ribosomes. Mature cytoplasmic ribosomes can also pay the ultimate price for cell survival by being targeted for bulk degradation by a specialized form of autophagy.

Degradation of Defective Ribosomes

Defects detected within pre-ribosomes are dealt with by the nuclear RNA degradation machinery. Catalytically this uses an exonuclease complex termed the exosome, but is likely to require polyadenylation of the defective species by exosome cofactors (Lubas *et al.*, 2011). It is interesting to note that the exosome is responsible for on-track endonucleolytic cleavage of pre-rRNAs during ribosome biogenesis (Sloan *et al.*, 2013b) as well as being the likely nuclease involved in mRNA degradation within the cytoplasm. This highlights the importance of (pre-) ribosome-exosome interactions which may be similar for each process.

Despite these nuclear surveillance mechanisms, defective ribosomal subunits can enter the cytoplasm. Here, 40S subunits undergo a proof-reading step before entering the pool of translating ribosomes (Strunk *et al.*, 2012; Lebaron *et al.*, 2012). This proof-reading was identified in yeast and is likely to be conserved to mammalian cells. However, the outcome of failure at this proof-reading step for both the defective 40S subunit and stress signaling remains to be elucidated. It is also unknown whether 60S subunits are proof-read in this way.

Both ribosomal subunits are also monitored for aberrations which may result from faulty biogenesis or stress induced damage. For the 40S subunit this process is recognized during translation elongation by stalling of the defective ribosome (Cole *et al.*, 2009). Degradation then follows a similar pathway to degradation of mRNA by no-go decay, involving endo- and exonucleases. In contrast, ubiquitinylation of aberrant 60S

Figure 7 Ribosome biogenesis as the foundation for ribosome function and stress. Throughout their lives (running from bottom to top) ribosomes respond to stress signaling (left) and are able to detect stress at its source (right). Ribosome biogenesis in the nucleolus is the foundation of ribosome stress. This process detects stress and has a severe response mechanism, signaling to p53 and other proteins capable of deciding cell fate. Simultaneously, nucleoli are responsive to stress signaling from kinases, sirtuins and alterations in their protein components. As well as carrying out these stress functions nucleoli assemble 40S and 60S subunits, which are exported to the cytoplasm to catalyze translation. Translation is regulated by some of the stress response pathways that also govern ribosome biogenesis. Accurately synthesized ribosomes are also required for activation of cap-independent initiation via IRESs, which is common following stress. Ribosome fidelity may also be important for the emerging roles of ribosomes in mRNA and protein quality control. This perhaps explains the strict surveillance of ribosome biogenesis and of mature ribosome quality, which feed into ribosome degradation pathways. Finally, ribosomes can still contribute to the cell in death, by undergoing ribophagy in times of stress to replenish biomolecule availability.

subunits drives their degradation by the proteasome (Fujii *et al.*, 2009). Ubiquitinylation presumably occurs upon RPs of the 60S subunits. Inhibition of the proteasome stabilizes defective 60S rRNAs indicating that their degradation is dependent upon proteasomal targeting (Fujii *et al.*, 2012). As such, the paradigm of RNA and protein management being split between the 40S and 60S subunits respectively is paralleled by subunit degradation mechanisms – degradation of the 40S uses RNA degradation pathways, whereas 60S degradation is driven by protein degradation pathways.

Ribophagy

Under nutrient stress the demand for biomolecules drives the shutdown of ribosome biogenesis and translation. However, severe nutrient stress may require further measures. One such mechanism is the bulk degradation of cellular components within cytoplasmic vesicles – a process called autophagy. Ribosomes contain both nucleic and amino acids, making ribophagy (autophagy of ribosomes) an attractive source of biomolecules. In yeast, both 40S and 60S subunits are substrates for ribophagy, with the 60S mechanism dependent upon a ubiquitinylation switch involving both ubiquitin proteases and ligases (Kraft *et al.*, 2008; Kraft and Peter, 2008). Supplementing the ubiquitin modulating enzymes in ribophagy is the Cdc48 protein (Ossareh-Nazari *et al.*, 2010). Ribophagy appears to be unbiased by ribosome function, but it is interesting to note that Cdc48 is also a component of the ribosome associated protein quality control complex (Brandman *et al.*, 2012), indicating multiple Cdc48

activities at the ribosome. 40S subunits are susceptible to ribophagy, but the markers for their degradation remain to be identified.

Conclusion

Ribosome stress is a complex system of two-way regulation, where potential stresses are detected both during the biogenesis and subsequent function of ribosomes. We have seen that ribosomal energy expenditure has necessitated their synergy with energy-stress signaling pathways. This has often been considered separately for ribosome biogenesis and for translation, despite some of the same stress pathways modulating both processes. Cells have evolved mechanisms to deal with stress at the local level of the translating ribosome (aberrant protein, mRNA or ribosome decay) as well as a fail-safe activation of p53 and other cell fate regulators linked to ribosome biogenesis. Synthesis of ribosomes evidently evolved as a closely monitored pathway, to which further arms of cell stress recognition have been added (Figure 7). The severity of the response to detection of stress within nucleoli, which is linked to alterations in ribosome biogenesis, may act to ensure the full ribosomal repertoire is in place for translation. It seems that cells employ the mantra of doing things right the first time to ensure fewer problems in the future.

Extra-Ribosome Functions of Ribosomal Proteins

DA Franklin and Y Zhang, The University of North Carolina, Chapel Hill, NC, USA

Introduction to Basic Ribosome Structure and Function

As discussed in other sections of this work, cells follow the central dogma of cell biology, which describes the conversion of template DNA to secondary messengers (mRNA), which are translated into the primary effectors (proteins). This complex process requires precise collaboration and rapid turnover of ribosomes, which are responsible for the coordination of mRNA transcripts, and charged tRNA molecules to form peptide bonds required for protein synthesis. Eukaryotes express 79 ribosomal proteins that combine with ribosomal RNA (rRNA) to form the large and small subunits of the functional ribosome (Boisvert *et al.*, 2007). The functions of ribosomal proteins in protein synthesis are discussed in other sections of this work. In this section, we explore the extra-ribosomal functions of these proteins. First, we provide a brief explanation of ribosomal assembly and canonical ribosome function. Then, we will address the regulation of ribosome biogenesis by both tumor suppressors and oncogenes. Finally, extra-ribosomal functions and the role of mutant ribosomal proteins in disease will be discussed with a focus on the ribosomal protein-MDM2-p53 pathway.

Ribosome Assembly

In actively dividing cells, ribosome biogenesis accounts for a significant portion of cellular resources. In yeast, and presumably in mammalian cells, upwards of 60% of total cellular resources are devoted to the rapid generation of ribosomes (Warner, 1999). Ribosome biogenesis occurs in the nucleolus, a condensed non-membrane bound section of the nucleus that contains a number of uncharacterized proteins and chromosomal DNA. The lack of a membrane barrier between the nucleolus and the nucleoplasm is unique among organelles, as it allows for the free exchange of molecules between these two compartments. Prior to transcription of ribosomal genes, tandem repeats of chromosomal rDNA genes are arranged in the nucleolar organizing regions (NOR). Upon establishment of the NOR, the 47S precursor rRNA is then transcribed by RNA polymerase I (RNA pol I) in the fibrillar center of the nucleolus and then further processed to form the mature 18S, 28S, and 5.8S rRNA's (Boisvert *et al.*, 2007). In contrast, the gene encoding the 5S rRNA is transcribed by RNA polymerase III (RNA pol III) prior to export from the nucleolus to the cytoplasm where it binds RPL5 to form the 5S ribonucleoprotein (RNP) (Szymanski *et al.*, 2003). Ribosomal proteins are transcribed by RNA polymerase II (RNA pol II) and are exported from the nucleus for translation. The majority of ribosomal proteins demonstrate basic isoelectric points, which facilitates their association with rRNA molecules found in the ribosome (Lempiäinen and Shore, 2009). After translation in the cytoplasm, the nascent ribosomal proteins are then imported back into the nucleolus for assembly of the large (60S) and small (40S) ribosomal subunits. In the absence of sufficient rRNA, many

ribosomal proteins are thought to form a negative feedback loop against their own transcription and translation to prevent aberrant accumulation of ribosomal proteins. For example, several ribosomal proteins including ribosomal protein L30 (RPL30), ribosomal protein S14 (RPS14), ribosomal protein L12 (RPL12) in *Caenorhabditis elegans*, and ribosomal protein S13 (RPS13) in humans have been shown to inhibit their own mRNA splicing thereby forming negative feedback loops, which can prevent excessive RP accumulation. Moreover, RPL2 and RPS28 have both been shown to shorten the half-lives of their own mRNA transcripts (Warner and McIntosh, 2009). RNA interference has been utilized in the study of various proteins after it was initially discovered that introduction of short double stranded RNAs silenced genes containing the homologous sequence in *C. elegans* (Fire *et al.*, 1998). Furthermore, short interfering RNAs (siRNA) of approximately 21–22 nucleotides can be introduced to cells to specifically decrease expression of a gene using the cells own machinery to degrade the double strand RNA complexes created by siRNA binding to specific mRNA transcripts (Elbashir *et al.*, 2001). Consistent with these observations, siRNA-mediated suppression of a single ribosomal protein within the small subunit of the ribosome (RPS) in HeLa cells can cause the concomitant suppression of the expression of other RPS proteins while having no effect on the expression of ribosomal proteins of the large subunit (RPL). The decreased expression of subunit-specific ribosomal proteins was also observed for siRNA-mediated knockdown of RPL protein expression suggesting that feedback inhibition can prevent the accumulation of subunit-specific ribosomal proteins to avoid stoichiometric imbalances (Robledo *et al.*, 2008). This method of auto-regulation could play an important role in preventing the activation of various stress pathways we will see later in this article.

Ribosome Biogenesis Can Be Inhibited Using Small Molecules

The high energetic demands of ribosome biogenesis require the cell to exert tight control over the process and allow for changes in flux through the pathway in response to a variety of cellular stresses. Low levels of the chemotherapeutic Actinomycin D (ActD) can be used to specifically inhibit rRNA transcription through RNA pol I independent of the DNA damage that is observed with higher concentrations of ActD (Iapalucci-Espinoza and Franze-Fernandez, 1979). Furthermore, another chemotherapeutic 5-fluorouracil (5-FU) can be used to inhibit all RNA synthesis, which inhibits ribosome biogenesis in a less specific manner (Longley *et al.*, 2003).

Ribosome Biogenesis Is Intrinsically Connected to Cancerous Growth

Tightly Regulated by Oncogenes

Cancer cell proliferation requires high levels of protein synthesis and correspondingly high levels of ribosome biogenesis.

A number of oncogenes such c-Myc, protein kinase B (Akt), and extracellular signal-regulated kinases (ERK) have been shown to upregulate ribosome biogenesis primarily by the regulation of rRNA transcription.

c-Myc is a general transcription factor that regulates the transcriptional activity of all three RNA polymerases (RNA pol I, II, and III) through various mechanisms. Briefly, c-Myc colocalizes with its binding partner Max to E-box sequences found within the promoter region of rDNA resulting in an increase in RNA pol I transcription (Grandori *et al.*, 2005). c-Myc also activates RNA pol III transcriptional activity through its association with TFIIB. The association between c-Myc and TFIIB is observed within the promoter regions of 5S rRNA and tRNA codons and correlates with an increase in the transcription of these genes (Gomez-Roman *et al.*, 2003). c-Myc regulation of RNA pol II transcription, which is responsible for the transcription of ribosomal proteins and other proteins associated with ribosome biogenesis, is evident based on the increased presence of c-Myc within RNA pol II promoter regions (Menssen and Hermeking, 2002). Recent studies have shown that c-Myc also regulates RNA pol II mediated transcription by increasing the rate at previously assembled complexes initiate transcription, which is known as pause and release regulation (Rahl *et al.*, 2010). Furthermore, c-Myc mediated increases in ribosome biogenesis play a central role in c-Myc-driven tumorigenesis as deletion of one allele of L24 or L38 inhibits the development of E μ -Myc driven lymphoma (Barna *et al.*, 2008).

The mechanistic target of rapamycin (mTOR) is an atypical serine/threonine protein kinase that regulates cell proliferation and survival through both mTOR complexes named mTORC1 and mTORC2 (Laplane and Sabatini, 2012). The PI3K-Akt-mTORC1 pathway directly regulates ribosomal protein and rRNA synthesis through the activation of S6 kinase (S6K), which phosphorylates RPS6. In non-Hodgkin lymphoma, RPS6 phosphorylation is associated with increased translation of 5' terminal oligo-pyrimidine (TOP) genes, which include ribosomal proteins, splicing factors, and translation elongation factors (Hagner *et al.*, 2011). mTORC1 also associates with either TIF-IA or upstream binding factor (UBF), a necessary cofactor in the initiation of transcription by RNA pol I, to upregulate rRNA transcription. mTORC1 is also involved in the processing and maturation of rRNA in the nucleolus (Mayer and Grummt, 2006).

The Ras-ERK oncogenic pathway coordinates with the c-Myc and Akt signaling axes to further increase ribosome biogenesis forming a complex network of oncogenes that positively regulate ribosome biogenesis. The Ras-ERK pathway has also been shown to increase expression of p90 ribosomal S6 kinase, which functions in a similar manner as mTOR-activated S6K to increase ribosome biogenesis (Roux *et al.*, 2007).

Repressed by Tumor Suppressors

In contrast to oncogenes, which upregulate ribosome biogenesis, tumor suppressors primarily inhibit this process. Increased expression of the tumor suppressor Rb directly inhibits ribosome biogenesis through its association with UBF in the nucleolus thereby preventing the proper assembly of the RNA Pol I transcription complex in mouse fibroblast cells (Hannan

et al., 2000). Similar to Rb, p53 also binds SL1, a member of the UBF transcription complex, in the nucleolus to inhibit RNA Pol I activity (Zhai and Comai, 2000). Other studies have shown that p53 also inhibits RNA Pol III through its direct binding of TFIIB, which results in the sequestration of TFIIB from active transcription complexes (Cairns and White, 1998).

The tumor suppressor ARF has been shown to inhibit ribosome biogenesis through multiple mechanisms. ARF can potentially activate p53 by binding and inhibiting MDM2; however, ARF can also inhibit ribosome biogenesis through p53-independent mechanisms. The gene mouse double minute 2 (MDM2) is the primary negative regulator of p53 and has been shown to bind directly to the N-terminal domain of p53 thereby physically preventing p53 association with DNA. ARF inhibits the phosphorylation of UBF independent of its ability to bind MDM2. Moreover, ARF inhibits rRNA processing by promoting the degradation of the NPM/B23 complex, a multifunctional complex in the nucleolus that plays a central role in ribosome biogenesis (Ayrault *et al.*, 2006; Itahana *et al.*, 2003).

Another tumor suppressor that inhibits ribosome biogenesis is the PTEN phosphatase, which dephosphorylates phosphatidylinositol-3,4,5-triphosphate resulting in the inhibition of the PI3K-Akt pathway (Li *et al.*, 2014). PTEN has also been shown to inhibit ribosome biogenesis in a more direct manner by blocking SL1-UBF complex recruitment to rDNA promoter regions (Zhang *et al.*, 2005). Current data suggest that cytoplasmic and nuclear pools of PTEN can coordinate the inhibition of ribosome biogenesis through two distinct mechanisms further demonstrating the importance of monitoring flux through the ribosome biogenesis pathway. Altogether, tight regulation of ribosome biogenesis is accomplished by oncogenes and tumor suppressor genes that appear to focus on the two signaling nodes S6K and UBF.

Ribosomopathies Are Associated with Increased Cancer Risk

Heritable genetic disorders associated with rDNA genes and ribosome assembly factors are collectively referred to as ribosomopathies. Studies investigating the mechanisms responsible for ribosomopathies have helped elucidate some of the non-ribosomal functions of ribosomal proteins. For example, studies on Diamond-Blackfan anemia (DBA) have revealed that the etiology of this particular disease is related to mutations in the RPS19 gene, and DBA patients also display an increased risk of acute myeloid leukemia (AML). More recent studies that have linked DBA with mutations in the genes *RPS24*, *RPS17*, *RPL35a*, *RPL5*, and *RPL11* have shown that this disease can lead to developmental defects in addition to the increased risk for cancer (Gazda *et al.*, 2008). In addition to DBA, a portion of chromosome 5 containing the *RPS14* gene is often deleted in patients with 5q syndrome, and this condition is similarly associated with an increased risk of AML (Ebert *et al.*, 2008). Ribosomopathies are not restricted to mutations in genes that encode ribosomal proteins, as mutations in factors that facilitate proper rRNA processing and subunit maturation are associated with Shwachman-Diamond syndrome and Treacher Collins syndrome (Freed *et al.*, 2010).

In the ribosomopathy cartilage–hair hypoplasia (CHH), mutations are commonly found in the *RMRP* gene, which contributes to rRNA processing in the nucleolus. A long-term follow-up study of CHH patients revealed a seven-fold increase in the occurrence of non-Hodgkin lymphoma and a ten-fold increase in the occurrence of basal cell carcinoma of the skin relative to a non-CHH population suggesting a direct connection between ribosome biogenesis and cancer initiation (Taskinen *et al.*, 2008). Furthermore, model organisms with alterations in ribosome biogenesis show an increased risk of cancer (Watson *et al.*, 1992; MacInnes *et al.*, 2008). In human tumors, ribosomal proteins are often overexpressed in breast, prostate, cervical, esophageal and liver cancers when compared with normal tissues (van Riggelen *et al.*, 2010). The deleterious effects of many ribosomopathies, particularly 5q syndrome, result in increased p53 activation, which is also observed in the context of ribosomal protein haploinsufficiency. Lenalidomide can be used to treat multiple ribosomopathies through a mechanism that is poorly understood but may involve the destabilization of p53 (Wei *et al.*, 2013). Ribosomopathies are associated with a wide array of phenotypes that cannot be fully explained by a decrease in protein synthesis. Thus, this class of diseases provides valuable physiological evidence of non-ribosomal functions for the factors involved in ribosome biogenesis.

Non-ribosomal Functions of RPs Independent of the MDM2-p53 Pathway

Studies on the non-ribosomal functions of RPs have been heavily focused on the ability of RPs to stabilize p53. However, many RP non-ribosomal functions have been described that do not directly involve p53 or its upstream regulator MDM2. Early studies of ribosomal proteins focused on RNA binding related extra-ribosomal functions as RPS1 was the first ribosomal protein identified to execute a non-ribosomal function. This observation was based on its ability to associate with a bacteriophage Q β peptide and endogenous peptides EF-Tu and EF-Ts to form the bacteriophage Q β replicase (Blumenthal and Carmichael, 1979). Subsequent studies have shown that bacterial ribosomal proteins RPS10 and RPS4 exhibit anti-termination effects on specific mRNAs when associated with the NUS complex after lambda phage infection (Luo *et al.*, 2008; Torres *et al.*, 2001). In another study, RPL4 was shown to bind to RNase E to modulate its activity in response to cellular stress (Singh *et al.*, 2009). Similarly, RPS3 has further been shown to exert a non-ribosomal function through its DNA endonuclease activity associated with the processing of UV-induced DNA damage (Kim *et al.*, 2006). Other studies of RPS3 have shown that this protein also functions as a critical component of the NF- κ B transcription complex in response to cellular stresses. The KH domain, which is present in many proteins that bind single-strand DNA or RNA, of RPS3 facilitates many of these extra-ribosomal activities (Wan *et al.*, 2007). RPL22 has been shown to bind to EBER-1 RNA of the Epstein–Barr virus; however, it remains unclear whether ribosomal proteins regulate viral RNA transcript stability or vice versa (Fok *et al.*, 2006). Through its basic N-terminus, RPL7 was shown to associate with and inhibit the

transcriptional regulation of the nuclear receptors that bind vitamin D and retinoic acid upon overexpression of RPL7 in yeast and at endogenous levels in human lymphoma cells (Berghofer-Hochheimer *et al.*, 1998).

As mentioned previously, tumor suppressors and oncogenes tightly regulate ribosomal protein levels and recent studies suggest that free ribosomal proteins also function as reciprocal regulators of cellular signaling. RPL11 has been shown to reduce cell proliferation through decreased ribosome biogenesis by inhibiting c-Myc-dependent transcription through RNA polymerases I, II, and III (Dai *et al.*, 2007). RPL23 has also been shown to bind and sequester nucleophosmin (NPM) from Miz1, a known inhibitor of c-Myc-dependent cell proliferation, to facilitate cell proliferation (Wanzel *et al.*, 2008). Another protein RACK1 was identified primarily for its role in cell signaling, but recent technical advances have demonstrated that RACK1 actually associates with the small subunit of the ribosome (Sengupta *et al.*, 2004). RACK1 is one of the few ribosomal proteins in which the non-ribosomal functions have been more thoroughly studied than its role as part of the ribosome (Warner and McIntosh, 2009). RACK1 functions as a scaffold protein that associates with a diverse array of binding partners including kinases, phosphatases, and G proteins among others to regulate a number of cellular processes, which inherently connects RACK1 to cancer development (Li and Xie, 2014). RPS3 and RPS6 bind HSP90, a protein chaperone, which prevents their own proteasomal degradation. Similarly, increased expression and nuclear localization of RPS3 appears to be involved in the induction of apoptosis in a caspase-dependent manner (Jang *et al.*, 2004); however, this function may involve p53 activation through the RP-MDM2-p53 pathway discussed later in this chapter. Overexpression of RPS29 causes an increase in apoptosis in non-small cell lung cancer cells, which coincides with increased expression of p53 and the pro-apoptotic p53 target gene Bax (Khanna *et al.*, 2003). RPL10 binds and inhibits the proto-oncogene c-Jun, a member of the AP-1 transcription factor and downstream target of the WNT and MAP kinase pathways (Montecarlo and Vogt, 1993; Nateri *et al.*, 2005).

Ribosomal proteins have also been implicated in multiple diseases such as Alzheimer's and type 1 diabetes. Studies on RPL10 have demonstrated that this RP binds presenillin-1, a regulator of β -amyloid peptides, the accumulation of which is associated with Alzheimer's disease. RPL10 binding to presenillin-1 appears to further modulate c-Jun transcriptional activity; however, whether this interaction plays a role in the development of Alzheimer's disease has not been confirmed (Imafuku *et al.*, 1999). Studies using large-scale integrative genomics to analyze human liver tissue have shown that reduced expression of RPS26 is associated with increased susceptibility to type 1 diabetes through a currently unknown mechanism (Schadt *et al.*, 2008). RPL22 has also been shown to bind histone H1 in *Drosophila melanogaster*, which could have implications in a variety of diseases, as histones are central regulators of gene transcription. Furthermore, the expression levels of RPL22 inversely correlate with overall mRNA transcription, as overexpression of RPL22 mimics the gene repression observed upon overexpression of histone H1 (Ni *et al.*, 2006; Table 1).

Table 1 Non-ribosomal functions of ribosomal proteins that occur independent of MDM2-p53

<i>Ribosomal protein</i>	<i>Function</i>	<i>References</i>
RPL4	Binds RNase E thereby modulating its activity	Singh <i>et al.</i> (2009)
RPL7	Inhibits transcription of vitamin D receptor and retinoid X receptor	Berghofer-Hochheimer <i>et al.</i> (1998)
RPL10	Binds and inhibits the proto-oncogene c-Jun	Montecarlo and Vogt (1993)
RPL10	Binds presenilin-1, biological function unknown	Imafuku <i>et al.</i> (1999)
RPL11	Inhibits c-Myc-driven RNA pol I-, II-, and III-mediated transcription	Dai <i>et al.</i> (2007)
RPL22	Binds Epstein-Barr viral RNA, which may promote viral life cycle	Fok <i>et al.</i> (2006)
RPL22	Binds histone H1 and overexpression decreases mRNA transcription	Ni <i>et al.</i> (2006)
RPL23	Inhibits Miz1 to facilitate c-Myc-driven cell proliferation	Wanzel <i>et al.</i> (2008)
RACK1	Scaffold protein involved in various cell signaling cascades	Li and Xie (2014)
RPS1	Associates with three other peptides to form the bacteriophage Q β replicase	Blumenthal and Carmichael (1979)
RPS3	DNA endonuclease activity responsible for processing UV-associated DNA damage	Jang <i>et al.</i> (2004)
RPS3	Component of NF- κ B transcription complex	Wan <i>et al.</i> (2007)
RPS4 and RPS10	Modulates transcription through its association with the NUS complex during lambda phage infection	Torres <i>et al.</i> (2001)
RPS26	Reduced expression correlates with an increased occurrence of type 1 diabetes	Schadt <i>et al.</i> (2008)
RPS29	Overexpression causes an increase in apoptosis that correlates with increased p53 expression	Khanna <i>et al.</i> (2003)

Ribosomal Protein-MDM2-p53 Pathway

MDM2-p53 Overview

Across all forms of cancer, p53 is the most commonly mutated gene with mutations observed in approximately 50% of tumors. The p53 stress response pathway results in the stabilization of p53 and an increase in p53 binding to the promoter regions of several target genes that largely suppress sources of genomic damage and tumor development. The canonical functions of p53 are cell cycle arrest, apoptosis and senescence. However, a recent knock-in mouse model harboring mutations that inhibit the acetylation of residues in p53 necessary for its activation following DNA damage has illustrated that the p53 tumor suppressive function requires more poorly understood p53 functions such as metabolic and reactive oxygen species (ROS) regulation (Li *et al.*, 2012). p53 is thought to enact diverse transcriptional programs that vary in severity according to the intensity of the cellular stress. For example, although p53 activation induces cell cycle arrest relatively quickly in response to several stresses, p53 upregulation of pro-apoptotic genes usually occurs only in response to the most severe cellular stresses. Moreover, studies have shown that the particular p53 transcriptional response can be altered depending on the duration of p53 expression (Purvis *et al.*, 2012).

As mentioned previously, MDM2 is the primary negative regulator of p53 through its ability to bind the N-terminal domain of p53 physically preventing p53 association with DNA. Furthermore, MDM2 acts as an E3 ubiquitin ligase that catalyzes the ubiquitination of p53, which leads to the nuclear export and subsequent proteasomal degradation of p53 (Pei *et al.*, 2012). The importance of MDM2-dependent regulation of p53 is evident in the fact that p53 activation requires the inhibition of MDM2-p53 association. DNA damage-mediated activation of the ATR-Chk1 or ATM-Chk2 pathways results in the phosphorylation of MDM2 and p53 in key residues that prevent their association. MDM2 inactivation can also be

triggered by oncogene activation, many of which increase the transcription of ARF, which binds MDM2 and inhibits p53 association (Hu *et al.*, 2012). p53 acetylation can also prevent MDM2-p53 binding and modulate p53 transcription through mechanisms that are not yet well understood (Li *et al.*, 2012; Figure 1).

p53 Activation Occurs in Response to Ribosome Biogenesis Inhibition

Hypoxia, heat shock and growth factor deprivation can activate p53 in a mechanism dependent on ribosome biogenesis inhibition (Zhang and Lu, 2009). DNA damage may also activate p53 through a similar mechanism as demonstrated by altered nucleolar structure following severe stress and highlighted by the disruption of nucleolar caps that form from condensation and segregation of nucleolar proteins and rRNA (Rubbi and Milner, 2003). p53 activation has been observed in response to changes in the expression levels of ribosomal proteins, suggesting that ribosome biogenesis requires precise stoichiometry of ribosomal proteins and other components involved in ribosome biogenesis to prevent p53 activation and facilitate cellular growth (Bursac *et al.*, 2014). p53 has been directly linked to ribosome biogenesis through the expression of a dominant negative form of the rRNA maturation factor Bop1, which mimics ribosomal stress and activates p53 (Pestov *et al.*, 2001). The activation of p53 was also observed after mutation or deletion of WDR12, which forms a complex with Bop1, further demonstrating that improper rRNA maturation and ribosome biogenesis signal through p53 (Holzel *et al.*, 2005). In actively dividing cells, the translation of ribosomal proteins in the cytoplasm places significant strain on nuclear import machinery to transport ribosomal proteins into the nucleolus for the proper assembly of the ribosomal subunits. Correspondingly, a transient decrease in the expression of importin 7 in human cancer cells inhibits ribosome biogenesis, disrupts nucleolar structure and activates p53 in an

Figure 1 RP-MDM2-p53 pathway model. Ribosomal proteins of the large (blue) and small (red) subunits normally interact within the nucleolus to form the large and small subunits. Upon nutrient deprivation or inhibition of rRNA synthesis by ActD treatment, the stoichiometry of ribosomal proteins and nucleolar structure is interrupted allowing free RPs to bind MDM2 in the nucleoplasm to activate p53. Oncogene activation causes the overproduction of RPs, which can then bind MDM2 and activate p53. NO, nucleolus; NP, nucleoplasm.

RPL11-dependent manner (Golomb *et al.*, 2012). Collectively, studies over the previous decade have demonstrated that disruptions at any step in the ribosome assembly pathway are sufficient to activate p53, which strongly supports a link between p53 and ribosome biogenesis. Interestingly, 5.8S rRNA was shown to covalently bind p53 at a phosphoserine residue near the N-terminus over twenty years ago further linking p53 to ribosome biogenesis; however, the *in vivo* role and significance of this interaction remains unknown (Fontoura *et al.*, 1992).

MDM2 Binds Ribosomal Proteins

MDM2 has been shown to bind several ribosomal proteins, including L5, L11, L23, L26, L37, S3, S7, S14, S15, S20, S25, S26, and S27. Ribosomal proteins L5 and L11 are thought to play a central role in p53 activation in response to ribosomal stress, as an imbalance in the stoichiometry of these ribosomal proteins is sufficient to activate the p53 stress response (Golomb *et al.*, 2014). Two main models of RPL11-MDM2 association have been suggested. The first model proposes that disruption of the nucleolus releases all ribosomal proteins into the nucleoplasm where the basic ribosomal proteins are free to bind the acidic domain of MDM2 in accordance with their binding affinity characteristics. A second theory suggests that ribosomal stress could cause an increase in the cytoplasmic pool of free ribosomal proteins either through increased translation of RPL5 and RPL11 or through the liberation of RPL5 and RPL11 from previously assembled ribosomes, after which these proteins are imported into the nucleus where they

can bind MDM2 (Deisenroth and Zhang, 2011). Ribosomal proteins also activate p53 through mechanisms independent of MDM2 association. For example, RPL26 binds to the untranslated regions of p53 mRNA and augments translation through the inhibition of the translation inhibitory nucleolin-p53 mRNA association (Chen *et al.*, 2012). Moreover, RPL11 has been shown to bind p53 response elements upon low levels of actinomycin D treatment, which results in an increase in p53-mediated transcription through the recruitment of the p53 co-activator p300/CBP (Mahata *et al.*, 2012).

Ribosomal proteins play an irreplaceable role in protein synthesis and the p53 stress response, therefore, the fact that deletion of RPS6, RPS19, or RPL11 is embryonic lethal in a number of model organisms is not surprising (Liu and Zhang, 2014). Mice that are haploinsufficient for RPL24 are viable, but these mice display developmental deformities referred to as the belly spot and tail phenotype, which is dependent on p53 expression. Surprisingly, RPL24 heterozygosity on a p53-null background results in embryonic lethality, which suggests that another layer of complexity exists in the interplay between ribosomal proteins and the p53 stress response (Barkic *et al.*, 2009). RPL11- and RPL5-MDM2 association occurs primarily in the central zinc finger domain of MDM2 and partially overlaps with the binding region of the tumor suppressor ARF (Honda and Yasuda, 1999). Analysis of an MDM2 knock-in mouse model harboring the human cancer-associated mutation C305F has been useful in extending our understanding on the role of the RP-MDM2-p53 pathway *in vivo*. Based on the observation that several human tumor mutations selectively target the central zinc finger of MDM2, the C305F mutation has been shown to selectively prevent L5 and L11 binding to

MDM2. Although we lack definitive proof, the fact that L5/L11 binding is selectively disrupted in tumors suggests that RP-MDM2 binding plays an important role in tumor suppression. Importantly, in the C305F mouse, the p53 response to DNA damage remains intact; however, ribosomal stress induced by low-level actinomycin D or starvation is unable to activate p53 because of the inability of MDM2 C305F to bind RPL5 and RPL11. This mouse model was further shown to harbor accelerated *Eμ*-Myc-induced lymphomagenesis, indicating that the RP-MDM2-p53 plays a role in preventing tumorigenesis independently of ARF (Macias *et al.*, 2010). Additional studies on the C305F mouse model have also shown that the RP-MDM2-p53 pathway is vital in sensing nutrient deprivation and activating lipid catabolism pathways in the mouse liver in response to acute starvation stress (Liu *et al.*, 2014). Thus, the C305F mouse model represents a unique opportunity to directly study the physiological role of the RP-MDM2-p53 pathway *in vivo*.

The RP-MDM2-p53 Pathway as a Putative Target in Cancer Therapy

Because cancer cells require a high rate of ribosome biogenesis and because approximately 50% of tumors retain wild-type p53, targeted inhibition of ribosome biogenesis could represent a valuable therapeutic option for many cancer patients. Drugs that specifically inhibit RNA pol I can reactivate wild-type p53 through the ribosomal stress pathway while simultaneously inhibiting ribosome biogenesis required for rapid cell growth. This two-fold tumor suppressive effect may be more effective than some of the current therapies. The small molecule CX-5461 inhibits SL1, which is a necessary cofactor for the RNA pol I transcription complex and correspondingly for rRNA transcription (Drygin *et al.*, 2011). The small molecule BMH-21 promotes the proteasome dependent degradation of RPA194, which is a member of the RNA pol I initiation complex, thereby inhibiting ribosome biogenesis without triggering the DNA damage response (Peltonen *et al.*, 2014). The effectiveness of these compounds in tumors expressing wild-type p53 is currently unknown, and further studies on this promising therapeutic avenue are needed.

Conclusions

Ribosome biogenesis is an energetically and logistically demanding process that is tightly regulated to facilitate controlled cell growth and survival. Mutations in the components associated with proper ribosome assembly are associated with ribosomopathies that display a diverse array of phenotypes that cannot be fully explained through altered protein synthesis. These observations suggest that ribosomal proteins exert several extra-ribosomal functions. In this section, we examined studies using a wide range of model organisms and techniques in an effort to obtain an overarching view of the function of ribosomal proteins outside of their niche in translation. We discussed some of the wide-ranging effects of the ribosome network on the cell with special attention to the

connection between ribosome biogenesis and the tumor suppressor p53.

Introduction

In the early 1960s, a group at MIT led by James Darnell was trying to characterize mRNA in mammalian cells when they found evidence for 'giant RNAs' in the dense fractions of sucrose gradients (Scherrer *et al.*, 1963). These 45S and 35S species were later proven to be metabolic precursors of ribosomal RNAs. The question of how these precursors gave rise to discrete ribosomal RNA species was hotly debated in the following decades (reviewed in Scherrer, 2003). Twenty years later, Thomas Cech, at University of Colorado, Boulder was studying the maturation of an rRNA precursor in *Tetrahymena* when he discovered that this particular RNA could catalyze its own processing in the absence of protein, a major breakthrough in molecular biology (Cech *et al.*, 1981).

Ribosomes are composed of two subunits. In prokaryotes, the large ribosomal subunit (LSU or 50S) contains the 23S rRNA and the 5S rRNA as well as over 30 proteins, and the

small ribosomal subunit (SSU or 30S) contains 16S rRNA and 21 proteins. In eukaryotes, the large, 60S subunit (LSU) contains 3 rRNA molecules (25/28S, 5.8S, and 5S) (Figure 1) as well as over 40 proteins. The small, 40S subunit (SSU) contains the 18S rRNA and over 30 proteins. Size variation of rRNAs among different species is due partly to expansion segments, which are sequence insertions in divergent regions of the rRNA ancestor. Over 200 accessory factors and 75 small nucleolar RNAs associate with the pre-ribosome throughout the process of ribosomal biogenesis.

Transcription of ribosomal RNAs usually involves two compartments: the nucleolus for the major rDNA unit and the nucleoplasm for 5S rRNA. Transcription of the major rDNA unit by RNA polymerase I generates a large precursor, 35S in yeast. 5S rRNA is normally transcribed by RNA polymerase III in the nucleoplasm with the exception of *Saccharomyces cerevisiae* where it is synthesized in the nucleolus. Association of the major precursor with 5S rRNA, ribosomal proteins,

Figure 1 Structure of *S. cerevisiae* mature ribosomal RNAs. The large subunit 25S rRNA is represented in light blue, 5.8S rRNA is depicted in green, and 5S rRNA is in red. The small subunit 18S rRNA is represented in orange. Helices in 18S rRNA important during processing and discussed in the text are shown in magenta (H33) and black (H44). H33 constitutes the 'beak' that forms during cytoplasmic maturation of 18S rRNA. Site D lies within H44 and is formed only after processing of the ITS1. PDB accession number: 3j77.

accessory factors, and processing complexes in the nucleolus constitutes the 90S pre-ribosome. This 90S complex is processed by cleavage of the 35S precursor, generating a 66S precursor of the 60S subunit, and a 43S precursor of the 40S subunit. These particles continue to mature as they transit from the nucleolus to the nucleoplasm. They are then exported to the cytoplasm where they become mature 60S and 40S subunits.

The functional importance of these reactions and the question of why so much energy is invested in transcribing 'wasteful' RNA sequences has been addressed in recent years with the generation of mutant strains lacking in specific enzymes in the processing cascade. For at least for a few 'model' organisms, we now have a clear picture of rRNA processing that details specific sequential modifications and their corresponding enzymatic complexes.

Ribosomal RNA Processing in Yeast

Cleavage and Folding of Precursor rRNA

Ribosomal RNA processing has been studied extensively in the budding yeast, *S. cerevisiae* (reviewed in Woolford and Baserga, 2013; Nazar, 2004). In this organism, the major unit of the ribosomal RNA genes (rDNA) is organized in tandem consisting of the SSU gene (18S) at the 5' end followed by two LSU genes (5.8S and 25S) at the 3' end (Figure 2). There are approximately 150 repeats of this unit on chromosome XII. Not all copies are transcriptionally active at any given time, but the redundancy protects against genomic instability. The extra sequences at both ends of each tandem repeat that are transcribed but are not present in the final products are the external transcribed spacers, 5'ETS and 3'ETS. The sequences separating the rDNA genes which are also transcribed but excised during processing are the internal transcribed spacers, ITS1 (between 18S and 5.8S) and ITS2 (between 5.8S and 25S). Exonucleolytic and endonucleolytic activities are required to remove these sequences as indicated in Figure 2 (letters A to E, with subscripts added based on the overall chronology of events). Processing also involves chemical modification of bases at specific positions (as described below).

Cleavage and modification of the precursor can start during transcription with about 80% of precursors being co-transcriptionally processed in yeast. The nascent RNA associates first with a series of ribonucleoprotein complexes collectively known as the SSU processome (Perez-Fernandez et al., 2007; Bernstein et al., 2004) in the nucleolus, required for the biogenesis of 18S rRNA. These RNPs have been classified according to their composition and time of assembly into several subcomplexes: the tUTP complex, the bUTP complex, the U3 snoRNP, the cUTP complex, the Bms/Rcl1 complex, and the Mpp10 complex. Later association with a different complex known as the A₃ cluster is necessary for processing of the LSU rRNAs. The A₃ cluster comprises the Pwp1 subcomplex, 6 interdependent A₃ factors, and 2 Dead-box proteins. For a comprehensive list of yeast protein factors involved in ribosome assembly, including processing, see (Woolford and Baserga, 2013).

For a majority of transcripts, once the polymerase has transcribed ITS1, the first processing events occur on sites denoted A₀ (on the distal end of the 5'ETS), A₁ (on the proximal end of the 5'ETS), and A₂ (in ITS1) (Figure 2). The last cleavage at site A₂ separates the 18S precursor (20S) from the remaining nascent transcript. This second transcript, containing a portion of ITS1, 5.8S, ITS2, 25S, and 3'ETS, is released by cotranscriptional cleavage by the RNase III Rnt1p at the B₀ site on the 3'ETS. Processing of the 3' end of this precursor to site B₂ generates 27SA₂. Those transcripts that are not co-transcriptionally processed at A₂ constitute the 35S pool. This 35S precursor is processed at the A₀, A₁, A₂, and B₂ sites, also generating 20S and 27SA₂.

The enzyme responsible for the cleavages at A₀, A₁, and A₂ is Rcl1p. This protein does not have a discernible *in vitro* activity on RNA, although it shares homology with 3' terminal phosphate cyclase enzymes. Rcl1p associates with Bms1pn, and disruption of this association leads to accumulation of precursor (Delprato et al., 2014). Disrupting an interaction between protein factors Krr1 and Faf1 in the 90S complex impairs cleavage at sites A₀, A₁, and A₂ (Zheng et al., 2014). The C-terminal domain of ribosomal biogenesis factor Rrp5 (Lebaron et al., 2013) is necessary for cleavage at A₀ and A₂ and its N-terminal domain is necessary for cleavage at A₃. Rrp5 and Rok1, a helicase, make direct contact with RNA helices within expansion segment 6 of the SSU (Martin et al., 2014). The majority of 27SA₂ precursors are cleaved at site A₃ by endonuclease MRP (Mitochondrial RNA Processing) generating 27SA₃. Exonucleases Rat1, Rrp17, and Xrn1 act in the 5' to 3' direction to trim this precursor to site B_{1S}, generating intermediate 27SB_S. This process requires Rat1 cofactor Rai1, as well as several other interdependent proteins belonging to the A₃ factors. An alternative fate for 27SA₂ is cleavage by an endonuclease at site B_{1L}, generating a longer intermediate 27SB_L. Eventually these two pathways generate two different pools of 5.8S in yeast cells, differing by ~7 nucleotides in their 5' ends (Henry et al., 1994). Both are incorporated in ribosomes and are competent for translation. Approximately 80% of the 5.8S rRNA precursor gets processed through the 5.8S_S pathway. These alternative forms have also been described in most but not all eukaryotes. Their significance is not clear.

No further cleavage occurs in the nucleolus. Intermediate 20S is transported to the cytoplasm as part of the pre-40S complex and cleaved at site D by Nob1p, assisted by Pno1/Dim2, generating its mature 3' end. An additional event in cytoplasmic maturation of 18S involves rearrangement and formation of the 'beak,' a protrusion of helix 33 (Figure 1). This step involves Hrr25 dependent phosphorylation and dissociation of ribosomal protein Rps3, which is close to helix 33. After formation of the beak, Rps3 is reincorporated to the 40S subunit (Schafer et al., 2006).

RNA folding participates in the regulation of these cleavage events by ensuring the sequential nature of certain steps. Prior to cleavage at A₂, folding of ITS1 prevents formation of helix 44 (Figure 1) at the 3' end of the 18S sequence. Cleavage site D lies within this helix (Lamanna and Karbstein, 2011). Once the A₂ site has been cut, this constraint on helix 44 is released, and Nob1p can recognize site D and generate the mature 3' end of 18S.

Figure 2 Processing of the major ribosomal RNA unit in *S. cerevisiae*. Sites of cleavage or exonucleolytic trimming are indicated with letters and subscript numbers. When known, enzymes responsible for these events are indicated in yellow ovals. The subcellular localization of different processing events is indicated on the right. There are two forms of 5.8S rRNA, 5.8S_s and 5.8S_L which differ by 7 nucleotides at their 5' ends. Subscript S and L denote small and long form of 5.8S rRNA. These two forms are generated by alternative pathways originating at 27SA₂. 27SB_s generates 5.8S_s and 27SB_L generates 5.8S_L. rRNA precursor species are named based on the sedimentation coefficient and the cut site that is used to generate the species.

Maturation of 27SB_L and 27SB_S continues in the nucleoplasm. A cleavage event within ITS2 at site C₂ separates the 5.8S precursor (7S_L or 7S_S) from the 25S precursor (25.5S). Two conformations of ITS2 are possible: a ring structure and a hairpin structure. The ring structure may form first and facilitate protein association. The hairpin structure contains a stem (III) that is essential for processing. This stem brings together distant sequences and allows for base pairing interactions between 5.8S rRNA and 25S rRNA (Cote *et al.*, 2002).

Exonucleolytic activity by Rat1p and Rrp17p in the 5' to 3' direction generates the mature 5' end of 25S. Several 3' to 5' exonucleases of the exosome like Rrp4p (De La Cruz *et al.*, 1998) act on the 3' end of 7S_L and 7S_S, reducing it to a point 30 bases downstream of site E. Exonuclease Rrp6p processes the remaining 30 nucleotides, generating mature 5.8S_S or 5.8S_L in the cytoplasm (Figure 2; Mitchell *et al.*, 1996).

Chemical Modifications of rRNA

The most common nucleolar modifications of rRNA are the additions of a methyl group at the 2' position of ribose (2'-O-methylation), and the linkage of uracil to ribose via carbon 5 in the pyrimidine ring, instead of nitrogen 1 (pseudouridylation). These modifications take place at specific positions, many of them in the vicinity of functionally relevant areas of the ribosome, such as the peptidyl-transferase center (Baudin-Baillieu *et al.*, 2009). There are several ways in which chemical modification of rRNA affects its biochemical properties. Methylation at the 2'-OH of the ribose moiety makes RNA more resistant to hydrolysis, favoring the 3' endo configuration. Isomerization of uracil changes the code of donor and acceptor groups for hydrogen bonds. Local base stacking can be enhanced by pseudouridylation. These chemical alterations of specific bases affect the efficiency of translation of the mature ribosome (Liang *et al.*, 2009). A number of small nucleolar RNA molecules (snoRNAs) dictates base specificity by hybridizing in the vicinity of the base to be modified (reviewed in Tollervey and Kiss, 1997). This base-pairing positions the enzymatic machinery correctly. Some snoRNPs such as U3 and U14 are essential for cleavage events in the 5'ETS at A₀ and A₁ and in ITS1 at A₂.

The class of snoRNA that leads to 2'-O-methylation possesses a conserved C/D box structure. Box C (RUGAUGA) hybridizes with box D (CUGA) forming the C/D motif. Not all box C/D elements are involved in methylation; some participate in cleavage events during processing and this may be their ancestral function. Box C/D snoRNAs associate with RNA binding protein Snu13, and proteins Nop56, Nop58, and Nop1, the catalytic methyltransferase that uses S-adenosylmethionine as donor (Watkins and Bohnsack, 2012).

snoRNAs that assist in pseudouridylation belong to the H/ACA box type. These snoRNAs fold in a typical hairpin-hinge-hairpin-tail secondary structure. Box H (ANANNA) is located within the hinge region, while box ACA (ACANNN) is at the 3' end of the tail. The rRNA to be modified hybridizes within loops in the hairpin regions. Box H/ACA snoRNAs form a complex with Nhp2 (an RNA binding protein), Nop10, Gar1 (which regulates loading), and Cbf5, the catalytic pseudouridylation synthase (Watkins and Bohnsack, 2012).

Chemical modification independent of snoRNPs also occurs in yeast rRNAs. A single C residue in the terminal helix of 18S rRNA is acetylated by Rra1p. This modification is important for the processing of the SSU precursor (Ito *et al.*, 2014). Two adenosine residues in 18S rRNA are converted to dimethyladenosines by Dim1p in the cytoplasm (Lafontaine *et al.*, 1998). This step is one of the few modifications common to eukaryotes and prokaryotes, and it yields mature 18S rRNA at the end of the processing pathway.

rRNA Processing in Other Eukaryotes

One major difference between *S. cerevisiae* and higher eukaryotes appears to be processing within ITS1. In *Xenopus*, two cleavage sites exist at the 5' and 3' ends of ITS1. Processing of these sites can occur in a different order, so there are different intermediates. One of these intermediates contains the 18S precursor as well as the ITS1 sequence in the 3', whereas a different intermediate contains the 28S precursor and the ITS1 sequence at the 5' end (Borovjagin and Gerbi, 2001, 2005).

In humans and other metazoans, an additional cleavage occurs in the 5'ETS (in the context of the SSU processome), upstream of cleavage sites A₀ and 1, 01 (Figure 3). Cleavage at this site is cotranscriptional and dependant on the assembly of the tUTP complex, requiring the bUTP complex and U3 snoRNP for high efficiency (Sloan *et al.*, 2014). Depletion of components of these complexes affects not only the rate of processing, but also the rate of transcription by polymerase I, indicating a tight connection between transcription and processing at the 5'ETS. The human homolog of Rat1p, XRN2, is involved in termination of transcription of the precursor, as well as in the degradation of fragments generated by cleavage at 01. Following cleavage at 01, a 45S precursor is generated. Cleavage at site 2 in ITS1 separates the precursor molecules for the LSU and SSU rRNAs. Alternative pathways lead to the production of a 41S intermediate via initial cuts at sites A₀ and A₁ on the 5'ETS. An additional intermediate, 18S-E, has also been described. This molecule could be generated by direct endonucleolytic cleavage at site E within the ITS1, or by the action of exonucleases acting on the 3' end of 21S in the 3' to 5' direction (Preti *et al.*, 2013). Although it is known that many factors are required for processing, only two enzymatic activities (5'-3' exonuclease Xrn2 and 3'-5' exonuclease ISG20L2) have been assigned to cleavage steps in human cells (Coute *et al.*, 2008; Wang and Pestov, 2011; Figure 3).

In the protozoan ciliate *Tetrahymena thermophila* the rRNA precursor is capable of self-cleavage to release the intervening sequence (IVS). A guanosine molecule performs a nucleophilic attack on the 5' splice site, creating a free hydroxyl group at the 3' end of the 5' exon. This group participates in a subsequent transesterification reaction at the 3' splice site, releasing the IVS (Price and Cech, 1988; Cech *et al.*, 1981). No protein cofactors are necessary for this reaction as indicated above.

Ribosomal RNA processing in early branching eukaryotes diverges farther away from the yeast pathway. In the parasite *Trypanosoma brucei*, the causative agent of African trypanosomiasis, the LSU rRNA (homolog to 25S rRNA in yeast) is cleaved to produce two large rRNAs (LSU 1 and 2) and four small rRNAs (SR1-4). In addition, the rRNAs of trypanosomes

Figure 3 Processing of the major ribosomal RNA unit processing in humans. Sites of cleavage and exonucleolytic trimming are indicated with numbers and letters. An extra 01 processing site exists in the 5'ETS in human rDNA. Known enzymes, responsible for these events are indicated in yellow ovals. The two alternative pathways and their convergence further downstream are shown.

contain unusually large expansion segments (Hashem *et al.*, 2013). Furthermore, the 5.8S rRNA is processed to generate a single species (equivalent to 5.8S_S) instead of the two species present in other organisms (Sakyama *et al.*, 2013). Despite the presence of some peculiarities, ribosomal biogenesis in

T. brucei requires both conserved and trypanosome-specific factors (Umaer *et al.*, 2014). Another example of unusual rRNA processing is the extensive fragmentation of the rRNA into 16 molecules, instead of 4, which occurs in the free living eukaryote *Euglena gracilis* (Schnare and Gray, 1990).

rRNA Processing in Prokaryotes

In prokaryotes, ribosomal RNA genes are organized in tandem and transcribed from the same promoter, generating a primary 30S transcript that contains the sequences for 16S, 23S, and 5S, as well as an internal tRNA in some cases (reviewed in [Shajani et al., 2011; Figure 4](#)). In *Escherichia coli*, this precursor is never observed experimentally in wild type cells, because cleavage by RNase III occurs co-transcriptionally. This initial processing step generates a 17S precursor (16S rRNA with a 115 nucleotide 5' terminal extension and a 33 nucleotide 3' terminal extension), a 23S precursor (with a 7 nucleotide 5' terminal extension and a 9 nucleotide 3' terminal extension), and a 9S precursor (5S rRNA with an 84 nucleotide 5' terminal extension and a 42 nucleotide 3' terminal extension). RNase

III needs double stranded RNA as a substrate ([Court et al., 2013](#)), so folding of the RNA precursor is necessary prior to initial cleavage. Base pairing between the 5' and 3' flanking regions of each rRNA generates the double stranded RNA recognized by RNase III.

The 17S precursor is further modified by RNase E and RNase G in the 5' end ([Li et al., 1999b](#)). Maturation of the 3' end is more complex and involves several 3' to 5' exonucleases: RNase II, RNase R, and polynucleotide phosphorylase (PNPase) ([Sulthana and Deutscher, 2013](#)).

The 23S precursor is cleaved at the 5' end by RNase G ([Song et al., 2011](#)) and at the 3' end by RNase T ([Li et al., 1999a](#)). Premature processing by RNase T is prevented by a CC dinucleotide ([Gutgsell and Jain, 2012](#)). Both RNase T and RNase III are more efficient when their substrates are

Figure 4 Ribosomal RNA processing in *E. coli*. The initial precursor contains the sequence for 5S rRNA (orange) in addition to 23S (red) and 16S rRNAs (blue), interspersed with a tRNA gene (purple). Cleavage sites are represented by vertical lines and the enzymes known to be responsible for cleavage events are indicated in yellow ovals.

precursors within a ribonucleoprotein complex rather than naked RNAs.

The 9S precursor is cleaved by RNase E (Mackie, 1998) on both ends, 3 nucleotides upstream and downstream of the mature terminal nucleotides. The 3 nucleotides at the 3' end are removed by RNase T. This step bears similarity to the processing of the 3' end of 23S precursor both in the enzyme involved as well as in the nature of the substrate, which in both cases is a short extension adjacent to a stem. The enzyme involved in the processing of the 5' extension of the 5S precursor has not been identified.

Mutant strains of *E. coli* that lack one or more of the enzymes involved in the processing of 16S rRNA are able to assemble ribosomes at the same rate as wild type cells, and these precursor-containing ribosomes are competent for translation (although their fidelity is reduced) (Sulthana and Deutscher, 2013). However, mutants that lack the enzymes involved in the processing of 23S rRNA exhibit a considerable delay in the rate of ribosome assembly, and precursors containing more than a few additional nucleotides at the 5' or 3' ends of 23S rRNA are not efficiently incorporated into ribosomes. It has been proposed that the existence of these extensions acts as a control mechanism linking rRNA processing and ribosome assembly.

Bacterial rRNAs are also chemically modified by methylation and pseudouridylation. However, prokaryotes do not use accessory RNAs equivalent to eukaryotic snoRNAs. Instead, the methyltransferases and pseudouridylate synthases recognize their substrates directly (Hage and Tollervy, 2004). Methylation of 16S rRNA by methyltransferases like ArmA and NpmA (acquired by horizontal DNA transfer) is responsible for resistance to aminoglycoside antibiotics by modifying the A site of the ribosome.

Mitochondria and plastids originated from ancient prokaryotic endosymbionts and, as such, their rRNA processing pathways share some characteristics with the prokaryotic rRNA processing pathways (reviewed in Bohne, 2014). There is great variability in genome organization of mitochondrial DNA across different organisms. In human mitochondria, two RNA species, 16S and 12S, together with approximately 80 nuclear-encoded proteins form the mitochondrial ribosome, which consists of a large 39S subunit and a small 28S subunit. The 16S and 12S genes on the circular mitochondrial genome are separated by a tRNA gene (V) and flanked on both ends by a tRNA gene (L at the 5' and F at the 3' end). The mitochondrial nucleoid associates with a ribosome assembly factor ERAL1 (Dennerlein *et al.*, 2010), proposed to act as a chaperone for nascent ribosomal RNA. A mutation in the tRNA gene between 16S and 23S can disrupt cleavage of the precursor transcript. Enzymes RNase P (Sanchez *et al.*, 2011) and ELAC2 (Brzezniak *et al.*, 2011) have been shown to be involved in the processing of the mitochondrial rRNA precursor.

5S rRNA Processing

5S rRNA is a molecule of approximately 120 nucleotides typically transcribed by RNA polymerase III. In higher eukaryotes, 5S rDNA genes are found in clusters in regions

which are distinct from the major unit rDNA repeats while in *S. cerevisiae* 5S genes are immediately adjacent to the rDNA repeats (reviewed in Ciganda and Williams, 2011). The initial transcript in yeast contains 3' extensions of 7–13 nucleotides. Rex1p is required for efficient processing of this extension (Van Hoof *et al.*, 2000). In the absence of Rex1p, other nucleases can process the 3' end of 5S rRNA with low efficiency. The trimming of the 3' end of 5S rRNA is not essential for yeast viability. An association between 5S rRNA and the La protein assists in the folding and maturation of the 3' ends of 5S rRNA (Wolin and Cedervall, 2002). Ribosomal protein L5 forms a stable complex with 5S rRNA (Lee and Nazar, 1997) prior to its incorporation to the precursor 90S particle. In *E. coli*, RNase T is also essential for the formation of the mature 3' of 5S rRNA (Li and Deutscher, 1995). In archaea, the 5' end of 5S rRNA can also be trimmed by tRNase Z, the same enzyme involved in the generation of the mature 3' end of tRNAs.

Human Diseases Caused by rRNA Processing Defects

rRNA processing is an essential and integral part of ribosome biogenesis. Given the universal importance of ribosomes in cell growth, division, and survival, it is not surprising that ribosomal biogenesis defects lead to severe congenital ribosomopathies (reviewed in Armistead and Triggs-Raine, 2014). The most common features of ribosomopathies include hematological defects, cancer predisposition, and small stature. Although ribosome assembly is an essential process in all cells, these diseases are often tissue specific. This fact highlights the underlying variability that exists in rRNA processing alternative pathways in mammalian cells, and how these pathways intersect with other developmentally regulated cellular pathways. In most cases, defects in processing lead to decreased rates of protein synthesis, and a decrease in cell proliferation. Although defects in large number of ribosomal proteins and ribosomal biogenesis factors lead to defects in rRNA maturation, here we discuss ribosomopathies caused by mutations in components known to be directly responsible for rRNA processing.

A number of disorders are caused by mutations in RMRP gene (Ridanpaa *et al.*, 2001, 2002) which encodes the RNA component of the MRP endoribonuclease. This snoRNP localizes to both mitochondria and the nucleolus and is involved in cleavage of mRNA and rRNA. The ortholog of RMRP in yeast is called *nme1*. Mutation of this gene affects endonucleolytic cleavage of 5.8S rRNA at the ITS-1 A3 site and as a result, 60S ribosomal assembly is disrupted (Schmitt and Clayton, 1993). In addition to rRNA processing defects, mutations in this gene can also affect cyclin B mRNA degradation, which leads to mitotic delay (Thiel *et al.*, 2005). Thus, mutations in *nme1* can impair both protein synthesis and cell cycle regulation.

Cartilage hair hypoplasia (CHH, MIM 250250), also known as metaphysical chondrodysplasia is one of these diseases. CHH, an autosomal recessive disorder, is a form of short limbed dwarfism with a height range of adults from 104 to 149 cm. The disease is also characterized by fine, sparse hair, defective T and/or B cell immunity, anemia, gastrointestinal anomalies, and susceptibility to cancer (Ridanpaa *et al.*, 2001;

Makitie and Kaitila, 1993). CHH was first described and is most frequently found in the Amish population where the incident rate is 1 in 1300 newborns. In people of Finnish descent, it affects about 1 in 20 000 live births. The RMRP gene defects can cause another related autosomal recessive disorder anauxetic dysplasia (AD, MIM 607095). Patients with AD showed more severe skeletal phenotypes than CHH with extreme short stature. However, they are not predisposed to malignancy (Thiel *et al.*, 2005). The RMRP mutations in CHH patients affect both rRNA and mRNA cleavage whereas AD patients are only deficient in rRNA maturation. These effects highlight the multiple functions of RMRP. In addition to CHH and AD, other mutations in RMRP have been implicated in additional rare inherited conditions such as metaphyseal dysplasia without hypotrichosis, kyphomelic dysplasia, and Omenn syndrome with a spectrum of symptoms generally involving the musculoskeletal system or the immune system (Martin and Li, 2007).

A missense mutation in another component of rRNA processing, Cirhin, causes North American Indian childhood cirrhosis (NAIC, MIM 604901) (Chagnon *et al.*, 2002). Cirhin is a homolog of a yeast tUTP component, UTP4, shown to be essential for 18S and 25S rRNA maturation in *S. cerevisiae* (Freed and Baserga, 2010). NAIC is a rare genetic disease that affects children of Native American descent in Quebec. It causes early progressive and irreversible liver damage, leading to death unless it is treated with liver transplantation.

As we gain further understanding of the ribosomopathies, we obtain more insights into the complexity of rRNA processing in humans.

Perspectives

What is the evolutionary advantage of a system that requires processing of its components to such a large extent, especially when it comes at the high energetic cost of synthesizing several RNA sequences (ETS and ITS elements) only to degrade them through maturation? One possible explanation is that processing provides directionality to ribosomal biogenesis. Formation of the 90S pre-ribosome in the nucleolus involves multiple protein–protein and protein–RNA interactions. Throughout ribosomal biogenesis, new protein–protein associations are formed and many are lost, as factors are released from the pre-60S and pre-40S particles. These interactions are essentially reversible. However, cleavage of RNA phosphodiester bonds is not, therefore making the process unidirectional and irreversible. Processing also provides a clock mechanism ensuring that enough time is given for appropriate folding and assembly of intermediates at different steps. Timing of incorporation and release of protein factors can be determined by sequential irreversible processing of the intermediates (Strunk and Karbstein, 2009).

Although our understanding of rRNA processing has greatly improved, much work is left to be done. More research is necessary to determine the structure and folding of the intermediates during processing. We are also starting to learn that alternative pathways of processing are not only organism dependent, but also vary among different cell types and metabolic states.

Conclusions

- Ribosomal RNA is transcribed as precursors with external and internal spacers.
- Processing of ribosomal RNA starts in the nucleolus, continues in the nucleoplasm, and ends in the cytoplasm.
- Exo and endonucleases remove the spacers with the help of accessory proteins.
- Specific residues are methylated or pseudouridylated.
- Chemical modifications rely on small nucleolar RNAs and their associated proteins.
- Some ribosomal RNAs can catalyze their own processing.
- Alternative pathways for the production of rRNAs are frequently used.
- Defects in rRNA processing are associated with human diseases.

Introduction

The ribosome is responsible for carrying out the final decoding step in gene expression, in which mRNA is translated into proteins. The overall structure and function of this molecular machine is universally conserved and consists of two subunits composed of ribosomal RNA (rRNA) and ribosomal proteins (r-proteins). The small subunit, which is 40S in eukaryotes and 30S in bacteria and archae, is responsible for codon recognition and pairing mRNAs with their cognate tRNAs (Wimberly *et al.*, 2000). The large subunit, which is 60S in eukaryotes and 50S in bacteria and archae, catalyzes the peptidyl transferase reaction to synthesize polypeptide chains (Ban *et al.*, 2000). Biogenesis of these enormous ribonucleoprotein complexes is a critical and energy-consuming task for all cells.

Although the overall architecture of the ribosome is conserved, eukaryotic ribosomes are significantly larger than their prokaryotic counterparts and contain proportionally more rRNA (65%) and less r-protein (35%) mass. The large, 60S subunit of *Saccharomyces cerevisiae* contains three rRNAs (25S, 5.8S, and 5S) and 46 r-proteins. The small, 40S subunit contains a single rRNA (18S) and 33 r-proteins (Ben-Shem *et al.*, 2011; Klinge *et al.*, 2011; Rabl *et al.*, 2011). The structures of both ribosomal subunits have been solved, providing an exquisite level of detail regarding their architectures and unprecedented insights into the mechanism of translation (Ramakrishnan, 2014). Despite these advances, we still understand relatively little about the assembly and transport pathways required to generate these molecular machines. This article will focus on what is currently known and will focus on budding yeast, which has been used to generate a general framework to further dissect this conserved biosynthetic pathway.

Eukaryotic ribosome assembly takes place in multiple cellular compartments: the nucleolus, the nucleoplasm, and the cytoplasm (Figure 1). This assembly process is a complex task that requires the coordination of RNA polymerases I, II, and III, as well as an efficient splicing machinery and efficient intracellular transport machinery. Surprisingly, despite this complexity, ribosome biogenesis is an incredibly efficient process, with yeast cells producing up to 60 ribosomes per second (Warner, 1999; Tschochner and Hurt, 2003).

Ribosomal Pre-rRNA Processing

Ribosome biogenesis begins co-transcriptionally on the 35S pre-rRNA (45S in mammals), which is synthesized by RNA Polymerase I (Figure 2; Dragon *et al.*, 2002; Woolford and Baserga, 2013). This transcript contains both 5' and 3' externally transcribed spacer (ETS) sequences, as well as the three rRNAs (18S, 5.8S, and 25S), separated by the internally transcribed spacer sequences ITS1 and ITS2. The yeast 90S particle (which is homologous to the mammalian SSU (Small SubUnit processome)) assembles on this precursor rRNA, forming structures first described by electron microscopy as 'Christmas trees' forming at the rDNA loci of *Xenopus* oocytes (Miller and Beatty, 1969; Dragon *et al.*, 2002; Grandi *et al.*, 2002). This precursor is cleaved first at site A0, generating the shorter 33S pre-rRNA. The second cleavage event occurs at site A1, generating the 32S pre-rRNA. The third cleavage site occurs at site A2 and generates the 20S and 27SA2. At this point, the 20S pre-rRNA is released to be further processed within the context of the 43S, which will become the mature 40S subunit, and is

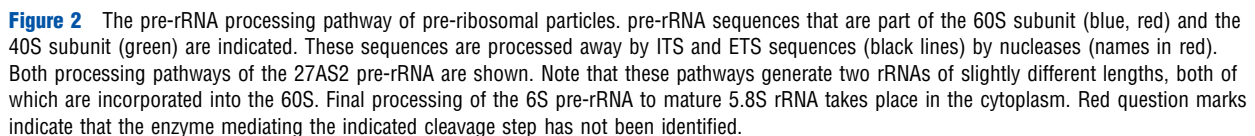

Figure 1 Eukaryotic ribosomes assemble along pathways that span the nucleolus, nucleoplasm, and cytoplasm. The 90S particle (orange) is built from the 35S pre-rRNA, which recruits assembly factors and small subunit r-proteins co-transcriptionally. Cleavage at site A2 separates the 90S into a pre-40S subunit (green) and a pre-60S subunit (blue), which follow independent maturation pathways. Assembly factors bind and drive maturation steps on pre-ribosomal particles, then are sequentially released. Final maturation of both the 40S and 60S pre-ribosomal subunits occurs in the cytoplasm. Question marks indicate uncertainty in the assembly pathway.

The remaining particles, containing 27AS2 pre-rRNA, recruit the 5S rRNA, which is transcribed by RNA polymerase III and bound by the biogenesis factors Rpf2 and Rrs1 and the ribosomal proteins uL18 (human L5) and uL5 (human L11) (Zhang *et al.*, 2007; nomenclature as in Ban *et al.*, 2014). Then, 27AS2 continues processing through one of the two pathways. The first pathway, comprising 85% of molecules, begins with

In addition to RNA cleavage events, eukaryotic ribosomes undergo multiple posttranslational RNA modifications, including isomerization of uridines to pseudouridines and

methylation (Woolford and Baserga, 2013; Lafontaine, 2015). Two classes of small nucleolar RNAs (snoRNAs) direct these modifications: the box C/D snoRNAs direct methylation, whereas the box H/ACA snoRNAs direct pseudouridylation. Although both modifications are more widespread in eukaryotes, occurring between 50 and 100 times each, they are also found in prokaryotes and archae. The functions of individual modifications remain unclear, and have been proposed to affect translational efficiency and rRNA structure (Baxter-Roshek *et al.*, 2007).

Trans-Acting Factors Involved in Ribosome Assembly

Unsurprisingly, ribosomal proteins themselves play critical roles in ribosome assembly. One study demonstrated that most 40S subunit proteins interact directly with the 35S pre-rRNA, though the interactions are weak. In addition, the small subunit proteins uS17 (yeast Rps11), uS4 (yeast Rps9), and uS15 (yeast Rps13) are required for early rRNA processing events and are homologous to the *Escherichia coli* 'primary binders' that mark the beginning of prokaryotic ribosome assembly *in vitro* (Held *et al.*, 1974). However, unlike their prokaryotic counterparts, eukaryotic ribosomes cannot self-assemble *in vitro* and require, in addition to ribosomal proteins, >200 additional *trans*-acting biogenesis factors.

Genetic screens in budding yeast and, in particular, the advent of tandem affinity purification (TAP) have yielded a long list of factors involved in ribosome assembly and export (Tschochner and Hurt, 2003). The majority of uncovered factors are essential, contrasting sharply with ribosome biogenesis in prokaryotes, which does not rely on essential biogenesis factors (Hage and Tollervey, 2004; Connolly and Culver, 2009). These evolutionarily conserved factors are generally thought to play roles in distinct maturation stages, after which they are released and recycled. In addition to scaffolds and RNA-interacting proteins, energy-consuming enzymes such as AAA-adenosine triphosphatase (ATPases), ABC-ATPases, guanosine triphosphatase (GTPases), and ATP-dependent RNA helicases are thought to be responsible for factor release, conferring directionality and irreversibility to the assembly process. Recent studies have begun to unravel the substrates, pre-ribosomal binding sites, and specific functions of these energy-consuming enzymes (Kressler *et al.*, 2012; Strunk *et al.*, 2012).

Two well-characterized examples of energy-dependent factor release are the essential AAA-ATPases Rix7 and Rea1, both required during 60S biogenesis. A related AAA-ATPase Drg1 is required for cytoplasmic maturation of pre-60S subunits (see Section Cytoplasmic Maturation of the 60S Subunit). Rix7, an early acting energy-consuming release factor, is responsible for early nucleolar 60S maturation. Although clear evidence remains elusive, this ATPase is proposed to be involved in the release of the assembly factor Nsa1. In turn, the release of Nsa1 is thought to require posttranslational modifications, which allow its recognition by Rix7. This energy-consuming release step is critical to facilitate the nucleolar to nucleoplasmic movement of 60S pre-ribosomal particles (Kressler *et al.*, 2008; Panse *et al.*, 2006).

Rea1 is involved at multiple maturation steps of the large ribosomal precursor (Ulbrich *et al.*, 2009; Bassler *et al.*, 2010;

Kressler *et al.*, 2012). Rea1 triggers the release of the biogenesis factors Ytm1 and Rsa4 (Nissan *et al.*, 2004; Ulbrich *et al.*, 2009; Bassler *et al.*, 2010). Release of Ytm1, along with its cofactors Erb1 and Nop7, has been proposed to trigger the displacement of neighboring assembly factors, conferring directionality to the ribosome maturation process (Nissan *et al.*, 2002, 2004; Ulbrich *et al.*, 2009). In addition to its nucleolar role, recent studies suggest that Rea1 is involved in a pre-60S nuclear checkpoint, releasing the GTPase Nug2 (Nog2) and allowing recruitment of the 60S export factor Nmd3. These observations suggest that Rea1 coordinates nuclear maturation and export of pre-60S particles (Matsuo *et al.*, 2014).

Many 40S biogenesis factors, such as the RNA dimethylase Dim1p, Dim2p, Enp1p, Hrr25p, Nob1p, the RNA helicase Prp43p, Rrp12p, Tsr1p, and Tsr2, required for 40S biogenesis are present within the 90S prior to A2 cleavage and release of the 20S pre-rRNA (Panse and Johnson, 2010). After A2 cleavage, additional proteins, including Ltv1p, Pfa1p/Sqs1p, Rio1p, and Rio2p, join the 20S pre-rRNA assembled within the pre-40S subunit (Panse and Johnson, 2010). Although the mechanisms by which these factors are recruited and the precise roles they play during biogenesis remain unclear, some details have been identified. For example, the kinase Hrr25 is thought to phosphorylate Enp1p, Ltv1p, and the small subunit protein uS3 (yeast Rps3p), perhaps to cause a structural change in these pre-40S particles and promote efficient transport through the nuclear pore (Schafer *et al.*, 2006). In addition, the essential RNA dimethylase Dim1p is required for early nucleolar processing events, though it also plays a later role in the cytoplasm (Lafontaine *et al.*, 1994, 1998) (see Section Cytoplasmic Maturation Events of the 40S Subunit).

In addition to assembly factors and energy-consuming release and remodeling factors, pre-ribosomal particles have been proposed to require the action of r-protein delivery factors, termed 'escortins.' One escortin, Tsr2, releases eS26 from its import receptor in a RanGTP-independent manner and then ensures its secure transfer to the earliest identified 90S pre-ribosome particle (Schutz *et al.*, 2014). Given the large influx of r-proteins into the nucleus and the inherent instability of these RNA-binding polypeptides, a network of escortins could keep r-proteins soluble until they are incorporated into pre-ribosomes.

Nuclear Export of Pre-Ribosomal Particles

Although translation is a cytoplasmic event, ribosome production begins in the nucleolus. Therefore, in addition to the import and nucleolar targeting of ribosomal proteins, ribosomal subunits must also be exported into the cytoplasm. All nucleocytoplasmic transport takes place through nuclear pore complexes (NPCs), which are macromolecular assemblies that span the double lipid bilayer of the nuclear envelope. The extraordinary size of pre-ribosomal particles (approximately 2 MDa) presents a particular challenge to the transport machinery (Ribbeck and Gorlich, 2002). In addition, the highly charged surfaces of these complexes must be shielded from the hydrophobic FG-repeats present within the NPC. Despite these obstacles, ribosome export is remarkably efficient, with growing yeast cells exporting about 25 pre-ribosomal particles

per minute per NPC (Warner, 1999). How the transport machinery manages to move these large, charged pre-ribosomal particles quickly and efficiently has been a topic of intense study, yielding the identification of multiple export factors, as described below.

In the 1990s, visualization assays based on green fluorescent protein (GFP)-tagging of ribosomal proteins and *in situ* hybridization against rRNAs were used to identify factors involved in pre-ribosomal subunit export (Hurt *et al.*, 1999; Moy and Silver, 1999; Stage-Zimmermann *et al.*, 2000; Milkereit *et al.*, 2003). These approaches identified several structural components of the NPC, the small GTPase Ran, Ran regulators, and the export receptor Crm1/Xpo1 as export factors for pre-60S and pre-40S subunits (Hurt *et al.*, 1999; Moy and Silver, 1999; Stage-Zimmermann *et al.*, 2000). However, these factors are not predicted to be sufficient for pre-ribosomal subunit export, since the rate of transport receptor shuttling is known to decrease as the size of a cargo increases (Ribbeck *et al.*, 1998). Transport of very large pre-ribosomal particles is predicted to be extremely slow, suggesting the requirement of multiple export factors to increase translocation rates.

Visual and genetic screens identified the nuclear export signal (NES)-containing adaptor Nmd3, which forms a trimeric complex with RanGTP and Xpo1 on the surface of the pre-60S subunit (Ho *et al.*, 2000; Gadal *et al.*, 2001). Using parallel approaches based on systematic RNA interference (RNAi) and ribosomal protein reporters, such visual screens have been extended to human cells. One such screen uncovered an essential role of the RanGTP-binding protein Exp5 as an export receptor for pre-60S subunits (Wild *et al.*, 2010). A structural modeling approach identified an additional export factor Rrp12, which binds both pre-ribosomal subunits and FXFG-repeat nucleoporins (Oeffinger *et al.*, 2004). Like RanGTP-dependent export factors, Rrp12 contains HEAT repeats, and therefore may interact with FXFG repeats using a similar mechanism. Intriguingly, Rrp12 was shown to interact with both GTP and guanosine diphosphate (GDP) forms of Ran. However, the mechanism by which Rrp12 promotes ribosomal subunit export and its regulation by Ran remain unknown.

Intriguingly, the essential mRNA export factor Mex67-Mtr2 (TAP-p15 in humans) also exports both pre-60S and pre-40S subunits (Segref *et al.*, 1997; Yao *et al.*, 2007; Faza *et al.*, 2012). The large subunit of the heterodimer, Mex67, consists of an N-terminal domain, a leucine-rich repeat (LRR), a nuclear transport factor 2 (NTF2)-like middle domain, and a C-terminal ubiquitin-associated (UBA-like) domain (Strasser *et al.*, 2000). Mtr2 shares structural features with NTF2 (Bayliss *et al.*, 2002) and heterodimerizes with the NTF2-like middle domain of Mex67 (Santos-Rosa *et al.*, 1998; Strasser *et al.*, 2000). Although Mex67 and Mtr2 do not rely on the RanGTP system, and have no structural similarities to karyopherins, the heterodimer also exports cargoes by interacting with FG-rich nucleoporins. To export mRNAs and pre-ribosomal subunits, Mex67-Mtr2 uses different binding surfaces. Interaction with pre-ribosomal subunits relies on loops within the NTF2-like domains of Mex67 and Mtr2 (Fribourg and Conti, 2003; Senay *et al.*, 2003; Yao *et al.*, 2007, 2008). Whether these loops directly interact with an exposed structured rRNA or a protein factor(s) on pre-ribosomal subunits still remains to be

determined. The NTF2-like domains of Mex67-Mtr2 and the UBA-like domain of Mex67 interact with FG-repeat nucleoporins to mediate mRNA and pre-ribosomal subunit export (Strasser *et al.*, 2000; Strawn *et al.*, 2001). The mRNA export factor Npl3 also plays a role in pre-60S subunit nuclear export (Hackmann *et al.*, 2011). Thus, the mRNA export machinery is partially adapted to carry both pre-ribosomal and mRNA cargoes. It is not yet known how the cellular pools of these factors are fractionated to participate in the nuclear export of mRNAs and pre-ribosomal subunits. Understanding the molecular basis of this allocation will reveal how the three export pathways cross-talk to deliver appropriate levels of mRNA and ribosomal subunits in the cytoplasm.

In addition to essential transport receptors, pre-ribosomal particles are also associated with nonessential transport factors that directly facilitate their translocation through the NPC channel, through interactions with nucleoporins. Although these factors are known to promote pre-ribosomal subunit export, it is not known whether they decorate every subunit during its export process, adding incrementally to export efficiency, or whether each subunit requires a quorum of factors, but not all, for efficient export. Two examples of these nonessential factors are described below.

The pre-60S export factor Arx1 is structurally homologous to methionine amino peptidases, which remove N-terminal methionines from nascent polypeptides as they emerge from the ribosome (Bradatsch *et al.*, 2007; Hung *et al.*, 2008). However, Arx1 lacks methionine amino peptidase activity, and mutations in the methionine-binding pocket impair pre-60S subunit export (Bradatsch *et al.*, 2007). When bound to the pre-60S, Arx1 occludes the exit tunnel of the 60S subunit and stabilizes the eukaryotic-specific rRNA expansion segment 27 (ES27) in an alternate conformation (Bradatsch *et al.*, 2012; Greber *et al.*, 2012). However, the details of how Arx1 mediates pre-60S export, as well as the function of its interaction with ES27 currently remain unknown.

The mRNA export factor Gle2 also mediates the export of pre-60S subunits, using a distinct, non-FG repeat binding mechanism (Occhipinti *et al.*, 2013). This factor interacts with late pre-60S subunits as well as the Gle2-binding-sequence (GLEBS)-motif of the nucleoporin Nup116. The Gle2-Nup116 interaction is required both to bind and export pre-60S subunits, but disruption of this interaction has no effect on mRNA export. Therefore, Gle2 appears to have dual functions in mRNA export and pre-60S export. This unique mechanism has been proposed to prevent kinetic delays during pre-60S translocation through the NPC, especially if cargoes have failed to recruit their optimal complement of export factors.

In addition to Gle2 and Arx1, Ecm1 and Bud20 have also been identified as factors involved in pre-60S biogenesis (Bradatsch *et al.*, 2007; Yao *et al.*, 2010; Altwater *et al.*, 2012; Bassler *et al.*, 2012). One major challenge in the field remains to identify the binding sites of individual export factors on pre-ribosomal particles. Together, these analyses will provide insight both into the structure and of pre-ribosomal export particles and the diversity underlying this export process.

Export of pre-40S subunits also relies on auxiliary factors such as the Xpo1 interacting proteins Ltv1, Dim2, and Rio2 (Zemp *et al.*, 2009). In addition, the conserved RanGTP-binding protein Yrb2 (RanBP3 in humans) has been identified

as a specific pre-40S export factor (Taura *et al.*, 1998; Moy and Silver, 2002). The identification of multiple, nonessential NES containing adaptors suggests that these factors play redundant roles to recruit the essential export receptor Xpo1. Such redundancy would act to guarantee Xpo1 recruitment, but remains to be demonstrated.

Cytoplasmic Events in Ribosome Biogenesis

Although the majority of ribosome biogenesis takes place in the nucleus, both subunits complete their maturation only in the cytoplasm. Completing ribosome biogenesis in this subcellular compartment potentially allows a system of checkpoints to ensure that only functional ribosomal subunits are allowed to participate in translation.

Cytoplasmic Maturation of the 60S Subunit

The cytoplasmic maturation pathway of the 60S subunit requires the release of multiple factors in a specific order (Figure 3; Lo *et al.*, 2010). These release events rely on factors present exclusively in the cytoplasm that associate only transiently with pre-60S particles (Panse and Johnson, 2010). The cytoplasmic maturation pathway begins with the release of Rlp24 by Drg1. Next, the ribosomal protein eL24 (yeast Rpl24) is incorporated onto the subunit and recruits Rei1. Together with Jjj1 and the ATPase Ssa1/Ssa2, these proteins cause subsequent Arx1 and Alb1 release. Only after the release of these two proteins, as well as formation of the acidic ribosomal stalk and correct assembly of the catalytic P-site, is the maturation factor Tif6 also released (Bussiere *et al.*, 2012).

The AAA-ATPase Drg1 initiates the earliest cytoplasmic maturation step on pre-60S particles, which is required for subsequent steps that release and recycle additional factors. Consequently, Drg1 catalytic mutants accumulate shuttling assembly factors Rlp24, Nog1, Arx1, and Tif6 on cytoplasmic pre-60S subunits (Pertschy *et al.*, 2007). A recent study demonstrated that Drg1 catalyzes Rlp24 dissociation, which is

essential for subsequent release events (Kappel *et al.*, 2012). Drg1 is recruited to a C-terminal region within Rlp24 that also stimulates its ATPase activity. Notably, Rlp24 release also appears to require the FG-nucleoporin Nup116. Thus, Drg1 has been hypothesized to provide irreversibility to the nuclear export step and initiate the cytoplasmic maturation pathway.

Release of the ribosomal-like protein Rlp24 is necessary to allow the ribosomal protein eL24 to assemble into the pre-60S subunit. This exchange allows recruitment of the zinc-finger protein Rei1, which triggers the next maturation event. Rei1 works in conjunction with the J-domain protein Jjj1 and the ATPase Ssa1/Ssa2 (Hsp70) to release Arx1 and its interacting partner Alb1 (Demoinet *et al.*, 2007; Meyer *et al.*, 2007). Interestingly, these data indicate that Arx1 has an inhibitory role in driving cytoplasmic maturation pathway of pre-60S subunits. Arx1 has evolved from methionyl amino peptidases (MetAPs) (Bradshaw *et al.*, 1998). Based on similarity of Arx1 to MetAPs, Arx1 was predicted to bind to the MetAP site on the ribosome, preventing MetAP binding. Indeed, Cryo-EM studies showed that Arx1 binds near the ribosomal protein uL25, which interacts with the signal recognition particle and the translocon, further suggesting that Arx1 plays an inhibitory role in the cytoplasmic maturation pathway (Dalley *et al.*, 2008).

Tif6 is another biogenesis factor that must be removed from the large subunit in the cytoplasm. This shuttling factor remains bound to cytoplasmic pre-60S particles, preventing their interaction with mature 40S subunits (Russell and Spremulli, 1979; Valenzuela *et al.*, 1982). The GTPase Efl1 and its cofactor, the Shwachman–Bodian Syndrome protein Sdo1, trigger release of Tif6 (Becam *et al.*, 2001; Senger *et al.*, 2001; Menne *et al.*, 2007). In *efl1* and *sdo1* mutants, Tif6 accumulates in the cytoplasm on late pre-60S subunits, and *tif6* mutations that weaken its affinity for the 60S subunit suppress the growth defects of *efl1* and *sdo1* mutants, providing strong genetic evidence that Tif6 is the primary substrate of Efl1 and Sdo1.

Interestingly, Tif6 also mislocalizes in *γvh1* mutants, which also display defects in stalk assembly (Kemmler *et al.*, 2009;

Figure 3 Cytoplasmic events required for 60S pre-ribosome maturation. Export factors are shown in yellow, and shuttling assembly factors are shown in green. Release of assembly factors Nog1 and Rlp24 by the ATPase Drg1 is thought to be the first step in the 60S pre-ribosome cytoplasmic maturation pathway. Rei1, J-domain protein Jjj1, and the ATPase Ssa1/Ssa2 are required for the release of Arx1 and Alb1. Stalk assembly relies on release of Mrt4 by Yvh1 and recruitment of uL10, which releases Yvh1. Tif6 release by Efl1 and Sdo1, as well as Nmd3 release by Kre35 follow stalk assembly. Factors that are released by unknown mechanisms (?) are listed in gray.

Lo *et al.*, 2009). During translation, the stalk functions in recruitment and activation of the GTPase eEF2 (Bargis-Surgey *et al.*, 1999). Given that Efl1 is closely related to eEF2, stalk assembly might play a similar role in biogenesis, recruiting Efl1 for the release of Tif6. These analyses suggest that the cytoplasmic maturation events in the 60S biogenesis are coupled and ordered sequentially from Drg1-dependent release of Rlp24 to Efl1-dependent release of Tif6 (Figure 3). Therefore, this pathway appears to rely on the coupled stepwise recruitment of cytoplasmic release factors to pre-60S subunits.

The essential NES containing adapter Nmd3 must also be released from pre-60S subunits in the cytoplasm. Both the ribosomal protein uL16 (yeast Rpl10) and the GTPase Kre35 (Lsg1) have been implicated in the release of Nmd3 (Karl *et al.*, 1999; Hedges *et al.*, 2005). Mutations in uL16 prevent release of Nmd3 from pre-60S subunits. Moreover, mutations in Kre35 that are predicted to disrupt its GTPase activity also block Nmd3 release in the cytoplasm. These results suggest that Kre35 triggers the binding of uL16 to the 60S, an event that is coupled to the release of Nmd3. However, the exact timing of Nmd3 release has not been elucidated.

Assembly of the stalk structure on the 60S subunit represents a critical step toward ribosome functionality. This structure is essential for the recruitment and activation of translation factors, in particular elongation factors. In yeast, the stalk region is composed of the ribosomal protein uL10 (yeast Rpp0) and two heterodimers of P1 (yeast Rpp1) and P2 (yeast Rpp2) (Berk and Cate, 2007). However, these proteins are not present in pre-60S subunits (Lo *et al.*, 2009; Kemmler *et al.*, 2009). Instead, the ribosomal-like protein Mrt4 is assembled into the pre-60S in the nucleus. Once the pre-60S is exported, the phosphatase Yvh1 catalyzes Mrt4 release, allowing the recruitment of uL10. However, the precise mechanism of Mrt4 release and the molecular events that lead to stalk assembly remains elusive (Lo *et al.*, 2009; Kemmler *et al.*, 2009).

In addition to these factors, a study combining genetic trapping, affinity purification and a targeted proteomic approach was used to characterize the proteome of 60S pre-ribosomes after nuclear export (Altwater *et al.*, 2012). This hybrid approach identified the factors Bud20, Nug1, Nsa2, and Rli1 as 60S-associated factors that are released in the cytoplasm after Drg1-mediated release of Rlp24. The functional significance of shuttling behavior of the identified assembly factors remains unknown. It could be that they participate directly in the transport and/or final functional proofreading of pre-60S subunits. The factors and mechanisms that release these shuttling assembly factors from 60S particles in the cytoplasm remain to be discovered.

Cytoplasmic Maturation Events of the 40S Subunit

The small pre-ribosomal subunit is accompanied to the cytoplasm by a handful of proteins, including Enp1, Tsr1, Ltv1, Dim1, Dim2, Nob1, Rio2, Hrr25, and Prp43 (Figure 4). These factors mediate both export and endo-nucleolytic cleavage of 20S pre-rRNA to 18S rRNA. This final cleavage event is an essential cytoplasmic maturation step that renders pre-40S particles translation-competent (Strunk *et al.*, 2011). How these shuttling factors are released from pre-40S subunits in the cytoplasm remains unclear.

Prior to 20S pre-rRNA cleavage, two adenine bases near the 3'-end of the future 18S rRNA are dimethylated by the essential dimethylase Dim1 (Lafontaine *et al.*, 1994). However, this modification is not essential, since processing of 20S pre-rRNA to 18S rRNA can still occur in the absence of dimethylation, forming functional 40S subunits. Dimethylation was suggested to play a role in fine-tuning of translation, as the catalytic inactive *dim1* mutant lacking 40S dimethylation displays increased antibiotic sensitivity (Lafontaine *et al.*, 1998). Multiple

Figure 4 Cytoplasmic events required for 40S pre-ribosome maturation. Export factors are shown in yellow, and shuttling assembly factors are in green. Release of shuttling factors and final pre-rRNA processing requires the ATPase Rio1 and the GTPase eIF5b as well as interactions with a mature 60S subunit. 20S pre-rRNA is processed in the cytoplasm to the final 18S rRNA by the endonuclease Nob1 within a 80S-like particle. Factors that are released by unknown mechanisms (?) are listed in gray.

energy-consuming ATPases (Prp43, Rio2, and Fap7) and the PIN-domain endonuclease Nob1 have been implicated in this late maturation (Clissold and Ponting, 2000; Geerlings *et al.*, 2003; Vanrobays *et al.*, 2003; Jakovljevic *et al.*, 2004; Lamanna and Karbstein, 2009; Pertschy *et al.*, 2009). Intriguingly, Nob1 becomes associated with 40S pre-ribosomes in the nucleus, suggesting that this protein is specifically activated in the cytoplasm. This activation of Nob1 in the cytoplasm occurs within an 80S-like particle formed between by the joining of a pre-40S subunit with a mature 60S subunit. Nob1 activation seems to also require the GTPase activity of the translation initiation factor Fun12/eIF5b and the ATPase Rio1 (Lebaron *et al.*, 2012; Strunk *et al.*, 2012; Turowski *et al.*, 2014).

Quality Control Mechanisms for Ribosome Assembly

Because accurate protein translation is critical to the cell, pre-ribosomes must undergo quality control prior to their release into the translating pool. Quality control begins in the nucleus, where aberrant pre-ribosomes are recognized and rapidly degraded by the exosome (Mitchell *et al.*, 1997; Allmang *et al.*, 2000). Although recognition depends in part on the poly-adenylating activity of the TRAMP complex, the precise recognition mechanism remains unclear (Dez *et al.*, 2006). A second quality control step is the cytoplasmic nonfunctional RNA decay (NRD) pathway, which targets improperly assembled pre-ribosomal subunits for degradation (LaRiviere *et al.*, 2006; Cole *et al.*, 2009). In addition to these quality control mechanisms, a cytoplasmic pathway exists to proof-read pre-ribosomes in the cytoplasm, preventing the premature binding of translation factors and, most likely, actively checking pre-ribosomal subunits for functionality.

Cytoplasmic 60S proofreading depends a coterie of factors that block the binding of ribosomal proteins, interactions with translation factors, or pairing with the 40S (Figure 3). Proteins that block r-protein binding include the ribosomal-like proteins Rlp24 and Mrt4, that act as 'placeholders' for the r-proteins eL24 and P0, respectively. Tif6 prevents binding of pre-60S particles to mature 40S subunits, ensuring that only properly assembled mature 60S subunits are able to engage their partners. In addition, the GTPase Efl1, which is required for Tif6 release, shares sequence similarity with the GTPase elongation factor eEF2, and has been proposed to check the integrity of the P-site for functionality (Bussiere *et al.*, 2012). Therefore, cytoplasmic release factors appear to be responsible both for releasing shuttling assembly factors and, simultaneously, testing ribosome function.

Similar to the 60S, quality control of the 40S relies on assembly factors that are thought to prevent the premature binding of initiation factors, mRNA, tRNA, and the 60S subunit (Figure 4). Based on cryo-EM studies of a late cytoplasmic pre-40S particle, Ltv1, Enp1, Rio2, Tsr1, Dim1, Pno1, and Nob1 binding sites have been identified (Strunk *et al.*, 2011). Ltv1 and Enp1 directly bind uS3 (yeast Rps3) on its solvent side, thereby blocking the mRNA channel opening. Rio2, Tsr1, and Dim1 bind the subunit interface, thus preventing joining of the mature 60S subunit and translation initiation factor eIF1A. Nob1 and Pno1 block the binding of eIF3 and thereby interfere with translation initiation. Therefore, these factors are likely to function, in part, by preventing premature translation initiation.

After the release of Rio2, Tsr1, and Dim1, the resulting pre-40S particle has been shown to interact with mature 60S subunits, forming an 80S-like particle *in vitro* and *in vivo* (Strunk *et al.*, 2012; Lebaron *et al.*, 2012). This translation-like interaction, which could test the ability of a pre-40S subunit to engage with 60S subunits, triggers the activity of Nob1 to cleave 20S pre-rRNA to mature 18S rRNA *in vitro*. In addition, the conserved translation initiation factor eIF5b/Fun12 is important for formation of the 80S-like particle (Lebaron *et al.*, 2012). After cleavage, the ABC-ATPase Rli1 is thought to cause dissociation of the 80S-like particle and Nob1 release (Strunk *et al.*, 2012). Thus, processing of the 20S pre-rRNA has been proposed to act both as a trigger for subunit maturation and as a quality control mechanism sensing translational competence. By constantly engaging with each other in the cytoplasm, ribosomal subunits may sense their 'decoding' ability to segregate and target faulty subunits for disassembly and degradation (Schutz and Panse, 2012).

Concluding Remarks

The biogenesis and nuclear export of ribosomal subunits is one of the most important energy-consuming tasks in a eukaryotic cell. The pathways responsible for 60S and 40S biogenesis are remarkably complex, requiring hundreds of evolutionarily conserved assembly factors in addition to the RNA and protein components of the ribosomal subunits themselves. Surprisingly for such a complex pathway, ribosome biogenesis and transport is also incredibly fast and at the same time efficient. Although the factors involved in this process have been largely delineated, their functions remain unclear, and there remains much to be learned about the detailed mechanism by which eukaryotic ribosomes are generated and transported through the cell. We anticipate a combination of genetic, cell-biological, biochemical, and high-resolution structural approaches in budding yeast will shed light on this poorly understood fundamental process.

Glossary

A site The point of entry for the amino-acyl tRNA except for Met-tRNA_i on the 40S ribosomal subunit.

Cap structure A 7-methylguanosine linked to the first nucleotide of eukaryotic mRNA by an inverted 5'-5' triphosphate bond. Its primary functions are to stabilize mRNA and to promote its translation.

Cistron A tract of DNA encoding a protein or a functional RNA molecule.

Codon A sequence of three nucleotides encoding a specific amino acid.

E site The exit site for deacylated tRNA on the ribosome.

Initiator tRNA A methionyl-tRNA (Met-tRNA_i) that base pairs with the AUG initiation codon and initiates protein

synthesis. It forms a ternary complex with eIF2 and GTP and binds the ribosomal P site.

P site The site on the 40S ribosomal subunit that accommodates Met-tRNA_i or peptidyl-tRNA.

Picornaviruses Small viruses belonging to the family Picornaviridae. Members of this family contain a single-stranded RNA genome of positive polarity. Many picornaviruses are important human and animal pathogens.

Poly(A) tail A stretch of adenine residues, generally of more than 100 nucleotides, at the 3' end of most eukaryotic mRNAs.

Translation A part of gene expression mechanism in which ribosomes synthesize proteins. It proceeds in three phases: initiation, elongation, and termination.

Introduction: The Canonical Cap-Dependent Mechanism of Translation Initiation in Eukaryotes

In eukaryotes, the formation of the 80S ribosomal initiation complex is the rate-limiting step in translation and a frequent target for translational control. On most mRNAs, translation is initiated by the scanning mechanism that involves the mRNA 5' cap structure (m⁷GpppN, where N is any nucleotide) and the cap-binding eukaryotic initiation factor (eIF) 4F (a heterotrimeric complex comprised of a cap-binding subunit, eIF4E, an ATP-dependent RNA-helicase, eIF4A, and a large scaffolding protein, eIF4G). The association of eIF4F with the 5' end of the mRNA is additionally stabilized by the poly(A) binding protein, which simultaneously interacts with eIF4G and the 3' poly(A) tail and confers on mRNA a circular conformation. The 5' end of the mRNA recruits the 40S ribosomal subunit preloaded with eIF1, eIF1A, eIF3, eIF5, and the ternary complex eIF2•GTP•Met-tRNA_i (termed as 43S complex) via the eIF3-eIF4G interaction. The 43S complex then scans the 5'-untranslated region (5'-UTR), aided by the unwinding of secondary structures using energy provided by ATP hydrolysis, until the AUG initiation codon in the optimal context (G/AXXAUGG, where X is any nucleotide) is encountered. In addition to eIF4A and its cofactor eIF4B, some other RNA helicases, such as DHX29, have been implicated in the removal of secondary structures during scanning (Jackson *et al.*, 2010; Hinnebusch, 2014). Subsequent joining of the 60S subunit accomplishes the initiation step of protein synthesis. This step requires hydrolysis of eIF2-bound GTP and the displacement of eIFs from the 40S subunit (promoted by eIF5 and eIF5B•GTP, respectively).

Although the mechanism of the 43S complex migration along the mRNA remains enigmatic even to this day, the scanning model is consistent with most experimental data on translation of eukaryotic mRNAs and nicely explains why these mRNAs are overwhelmingly monocistronic. Accordingly, this

model has not undergone substantial revision since its original proposal by Kozak (1978).

Internal Ribosome Entry Site-Mediated Translation Initiation

Discovery

The first exception to the 5' cap-dependent scanning model of translation initiation emerged from the studies of picornaviruses, which possess naturally uncapped, but yet efficiently translated RNA genomes. Other features of picornavirus RNAs that are not compatible with the cap-dependent scanning mechanism of translation are the presence of unusually long (610–1500 nt) and highly structured 5' UTR with multiple nonfunctional AUG triplets that are poorly conserved between strains. Furthermore, inactivation of the eIF4F cap-binding protein complex after picornavirus infection, which occurs either as a result of eIF4G cleavage or dephosphorylation and activation of eIF4E-binding proteins (4E-BPs), does not impede but rather stimulate the translation of viral mRNAs while effectively shutting off cap-dependent host cell protein synthesis.

In 1988, a landmark discovery explaining this distinct regulation of picornavirus genome translation was made in the laboratories of Nahum Sonenberg and Eckard Wimmer. In these experiments, internal segments of the 5' UTRs of poliovirus (PV) and encephalomyocarditis virus (EMCV), referred to as internal ribosome entry site (IRES) or ribosome landing pad, were shown capable of initiating translation independently of the cap structure (Jang *et al.*, 1988; Pelletier and Sonenberg, 1988). Soon after this discovery, IRES elements were found in the genomes of other picornaviruses as well as in many non-picornavirus mRNAs of both viral and cellular origin.

Assay

IRESs are typically identified by inserting the mRNA 5' UTR between two cistrons of a bicistronic mRNA (Figure 1). Efficient translation of the second cistron, even when the first cistron is not translated, such as when preceded by a stable stem loop structure or in poliovirus (PV) infected cells, provides a proof for 5'-end independent internal ribosome loading onto the 5' UTRs (Jang *et al.*, 1988; Pelletier and Sonenberg, 1988).

Although the use of bicistronic reporter constructs (usually dual *Renilla* luciferase and firefly luciferase reporter gene constructs) is considered to be the 'gold standard' for detecting of IRES activity, there are several caveats to be considered when interpreting the data. For example, the apparent IRES activity of some cellular mRNA 5' UTRs in the bicistronic construct assay, could be explained by the generation of aberrant monocistronic mRNAs due to cryptic transcription or the use of cryptic splice acceptor sites within the candidate IRES segments (see below).

As an alternative to the method of bicistronic constructs, IRESs can be identified by their ability to direct translation of downstream cistrons in circular RNAs (Chen and Samow, 1995).

Viral IRESs

Classification

A large number of positive strand RNA viruses, such as picornaviruses, use IRES-mediated translation to escape translational competition with the capped cellular mRNAs. Based on their structure and initiation factor requirements, viral IRESs are classified into four major types: (1) *Picornaviridae* enterovirus and rhinovirus (i.e., PV) IRESs, (2) *Picornaviridae* cardio-, aphtho-, and parechovirus (i.e., EMCV) IRESs, (3) Hepatitis C virus (HCV), pestivirus (i.e., classical swine fever (CSFV)) and other HCV-like IRESs, and (4) the dicistrovirus (i.e., cricket paralysis virus (CPV) intergenic region (IGR) IRESs (Hellen, 2009).

Unclassified viral IRESs include the picornavirus hepatitis A virus (HAV), the retrovirus human immunodeficiency virus 1 (HIV-1) and mRNAs of DNA-containing herpesviruses. Some RNA-containing plant viruses were also reported to contain IRES (Lopez-Lastra *et al.*, 2005). For representative viral IRESs, see Table 1.

Structure and mechanism

There is no structural similarity between different types of viral mRNA IRESs. However, despite their structural and functional

Figure 1 Schematic representation of the bicistronic construct assay. (a and b) In mRNAs transcribed from bicistronic constructs, the first cistron is translated by a cap-dependent scanning mechanism while translation of the second cistron depends on the presence of IRES in the intercistronic spacer. (c) Ribosome recruitment by IRES is independent of the first cistron expression. A 5'-UTR sequence is qualified as IRES if it significantly increases the Cistron-2/Cistron-1 expression ratio after insertion in the construct. For simplicity, the diagram does not show the 60S ribosomal subunits, eIFs and ITAFs, which participate in these processes.

differences, all four types of IRESs share a common feature, which is the ability to interact with one or more canonical components of the translational machinery, such as eIF4G, eIF3, or 40S ribosomal subunit (Figure 2).

Type 1 and 2 IRESs

The core IRES sequence of picornavirus RNA genomes is ~450 nt in length and consists of five domains, designated as II–VI and H–L in Type 1 and 2 IRESs, respectively. Secondary

structure predictions for picornavirus IRESs are fairly robust, as being validated by mutagenesis and functional assays. Secondary structure, and to some degree primary structure, is conserved within each type. However, sequence similarity between Type 1 and 2 IRESs is limited to a 3' terminal Y_n - X_m -AUG motif (where Y_n is an oligopyrimidine tract and X_m is a 18–20 nt spacer between Y_n and an AUG triplet). In EMCV, translation starts at the 3' terminal AUG of the IRES, while in foot-and-mouth disease virus (FMDV) both this and the next downstream initiator AUG is used. In PV and human rhinovirus (HRV), the initiator AUG is spaced out from the 3' border of the IRES by ~160 and ~30 nucleotides, respectively, so that the 43S complex must scan downstream from the silent AUG to reach the initiation codon. In Type 1 IRESs, the intact Y_n - X_m -AUG motif is important for initiation at the downstream AUG. Even small alterations of this motif impair IRES activity and viral growth (Pilipenko *et al.*, 1992). Structural elements upstream of the Y_n - X_m -AUG motif can also modulate PV IRES activity.

An important functional distinction between Type 1 and 2 IRESs concerns their ability to function in a rabbit reticulocyte lysate. While Type 2 IRESs are fully active in this system, translation from Type 1 IRESs is inefficient unless the lysate is supplemented with extracts of nucleated cells (see below).

Type 3 HCV-like IRESs

The ~300 nt-long HCV IRES encompasses three main structural domains, which adopt a tertiary fold (Honda *et al.*, 1999). The negative effect of several domain mutations on IRES activity is averted by compensatory mutations, which validates the proposed base pairing. The AUG initiation codon is located near the 3' end of the IRES. By now, many three-dimensional (3-D) structures of HCV and CSFV IRESs have been solved using NMR and X-ray crystallography (Berry *et al.*, 2011). The cryo-EM studies demonstrated that HCV IRES binds to the solvent-exposed side of the 40S subunit in extended conformation, docks its domain into the ribosomal exit (E) site and places the initiator codon in the ribosomal P site (Spahn *et al.*, 2001). Despite their ability to establish binary complexes with the 40S subunit, both HCV and CSFV IRESs require a limited set of eIFs to initiate translation (see below).

Importantly, the 40S subunit undergoes significant conformational changes following interaction with Type 3 IRESs (Fraser and Doudna, 2007). It is presumed that these changes promote entry, positioning and fixation of mRNA in the ribosomal decoding channel as well as subunit joining.

Type 4 Dicistroviridae IGR IRESs

The 190–220 nt-long IGR IRESs of dicistroviruses, which are located between the cistrons for structural and nonstructural proteins, adopt a tightly folded globular structure with two conserved stem-loops and three essential pseudoknots (Costantino *et al.*, 2008). Remarkably, these small IRESs do not require any initiation factors, the initiator Met-tRNA_i or a proper AUG initiation codon to assemble elongation-competent 80S initiation complexes.

The CrPV IRES binds directly to 40S subunits or 80S ribosomes where it occupies the inter-subunit space and mimics the base-paired initiation codon and anticodon in

Figure 2 Simplified representation of Type 1, 2, 3, and 4 IRES secondary structure elements and their interaction with the components of the translational machinery. The IRES stem-loop structures, II–VI in PV-1, H–L in EMCV, and II–IV in HCV, and pseudoknots (PK), I–III in CrPV IGR, are indicated. Red rectangles indicate the positions of the AUG and GCU start codons in mRNAs bearing Type 1–3 and Type 4 IRES, respectively. In Type 1 and 2 IRESs, Yn-Xm-AUG represents the 3'-terminal oligopyrimidine tract-AUG motif. Data from Jackson, R.J., 2013. The current status of vertebrate cellular mRNA IRESs. *Cold Spring Harbor Perspectives in Biology* 5, a011569 and Kieft, J.S., 2008. Viral IRES RNA structures and ribosome interactions. *Trends in Biochemical Sciences* 33, 274–283.

the ribosomal P site (Wilson *et al.*, 2000; Jan, 2006). Cryo-EM visualization of the CrPV IRES bound to ribosomes along with biochemical data point to the decisive role of the ribosomal protein rpS25 for IRES binding and indicate that IRES elements manipulate the ribosome to functionally replace initiator Met-tRNA_i and translation factors (Muhs *et al.*, 2011).

During initiation on CrPV IRES, the first codon to be decoded (alanine or glutamine triplet) is located in the A site, and the cognate amino-acyl tRNA is recruited to the A site by eukaryotic elongation factor 1 (eEF1). Amino-acyl tRNA is then translocated to the P site with the aid of eEF2 (Pestova and Hellen, 2003). This step is often referred to as pseudo-translocation, since in contrast to conventional amino-acyl tRNA translocation it occurs before peptide bond formation (Figure 3).

Roles of initiation factors

Canonical eIFs

For the most part, IRES-mediated translation requires fewer eIFs, as compared to cap-dependent translation (Figure 4). Moreover, the ability of Type 4 IRESs to directly interact with the 40S ribosomal subunit circumvents the requirement for all canonical eIFs.

Type 1 (PV), Type 2 (EMCV), and Aichivirus (AV) IRESs do not interact with the 40S subunit directly, but rather through their high-affinity eIF4G-binding sites. These IRESs make use of all the canonical eIFs, with the exception of eIF4E (i.e., eIFs 1, 1A, 2, 3, 4A, 4B, 4G, 5 and 5A), to initiate translation (Pestova *et al.*, 1996; Sweeney *et al.*, 2013). The middle segment of eIF4G that retains eIF4A and eIF3 binding sites is sufficient for initiation complex formation on these IRES.

Figure 3 Translation initiation by Type 4 IRESs. (a) Simplified representation of CrPV IRES. (b) The IRES sequentially interacts with the 40S and 60S ribosomal subunits to form the 80S initiation complex. (c) Alternatively, the IRES can bind a preformed 80S ribosome. (d and e) The delivery of the Ala-tRNA to the A site promotes pseudotranslocation with the resulting formation of the elongation-competent 80S complexes. The participation of elongation factors, EF1 and EF2, in initiation of translation by CrPV IRES is also shown. For simplicity, the ribosomal E site is not shown. Data from Jan, E., 2006. Divergent IRES elements in invertebrates. *Virus Research* 119, 16–28 and Kieft, J.S., 2008. Viral IRES RNA structures and ribosome interactions. *Trends in Biochemical Sciences* 33, 274–283.

Initiation on EMCV IRES begins with specific binding of eIF4G to the J-K stem-loops, which is stimulated by eIF4A (Kolupaeva *et al.*, 2003). Initiation on PV IRESs follows a similar pathway, and involves interaction of eIF4G/4A with the basal half of Domain V (de Breyne *et al.*, 2009). The PABP/3'-end poly(A) complex strongly potentiates Type 1 IRESs, presumably by contacting eIF4G and increasing its affinity for the IRES (Svitkin *et al.*, 2001). Mutations made in

the eIF4G/4A binding domain that weaken its secondary structure decrease the efficiency of translation of PV mRNAs *in vitro* and constitute the basis of attenuation of all three Sabin PV vaccine strains (Svitkin *et al.*, 1988; Minor, 1992; Ochs *et al.*, 2003). Conservation of the stem-loop structures in other picornavirus IRESs could be also important for optimal IRES function. The recruitment of eIF4G by Type 1 and 2 IRESs, however, is not sufficient for initiation since the borders

Figure 4 Different pathways of IRES-mediated translation in comparison with cap-dependent translation. For simplicity, only the first most diverse step of the pathways, that is, the recruitment of the 40S ribosomal subunit is shown.

of these IRESs extend far upstream of the eIF4G binding sites. The functions provided by the upstream regions of Type 1 and 2 IRESs remain largely unknown.

In contrast to Type 1 and 2 IRESs, Type 3 (HCV-like) IRESs recruit the 40S ribosomal subunit without the aid of the eIF4G/4A adaptor. The 48S pre-initiation complex on these

IRESs can be formed solely with a 40S ribosomal subunit, Met-tRNA_i, and eIF2 (Pestova *et al.*, 1998). The HCV-like IRESs are capable of establishing multiple contacts with the 40S subunit and eIF3 leading to the positioning of the initiation codon into the ribosomal P site. After base pairing of the initiator AUG with the anticodon of eIF2-bound Met-tRNA_i, a 48S initiator complex is formed. Thus, the factor-less recruitment of the small ribosomal subunit by Type 3 IRESs is akin to that used by prokaryotic mRNAs.

The role of eIF3 in translation initiation by Type 3 IRESs is not clear. Recent cryo-electron microscopy (cryo-EM) 3-D structures of the complex between the 40S subunit, eIF3, and HCV-like CSFV IRES indicate that eIF3 is displaced from its ribosomal position in the 43S complex to establish a new interaction with the apical region of domain III of the IRES (Hashem *et al.*, 2013).

Alternatively, eIF5B (an analog of bacterial IF2) can promote Met-tRNA_i binding to Type 3 IRES-40S complexes, resulting in the assembly of elongation-competent 80S ribosomes (Pestova *et al.*, 2008; Terenin *et al.*, 2008). This eIF2-independent mode of translation might be predominant when eIF2 is inactivated as a result of eIF2 α phosphorylation in response to viral infection or other stresses.

IRES transacting factors

Several RNA-binding proteins that are dispensable for cap-dependent translation, termed IRES transacting factors (ITAFs), modulate IRES activity by the mechanisms that are not well defined. First evidence for ITAFs was provided by the demonstration that HeLa cell extracts strongly stimulate the translation of PV RNA from the authentic initiation site, while reducing the incidence of abnormal internal initiation events, in rabbit reticulocyte lysates (Brown and Ehrenfeld, 1979; Dörner *et al.*, 1984). One of these stimulatory factors was purified and identified as La autoantigen (Meerovitch *et al.*, 1993). polyC binding protein 2 (PCBP2), SRp20, polypyrimidine tract binding protein (PTB), upstream of N-ras (Unr), and hnRNPA1 were also reported to activate Type 1 IRESs (Fitzgerald and Semler, 2009; Jackson, 2013). However, *in vitro* reconstitution of the 48S initiation complex formation on Type 1 IRESs did not reveal the requirement for these ITAFs except for PCBP2 (Sweeney *et al.*, 2013). Type 2 EMCV IRES is activated by PTB, while FMDV IRES requires PTB and the cell-cycle dependent protein ITAF45. Even the HCV IRES, which directly interacts with the 40S subunit, was suggested to be regulated by ITAFs, such as PTB, PCBP2, La, hnRNP D, and hnRNP L.

Mechanistically, ITAFs are thought to function as RNA chaperons that assist IRESs to adopt a functionally active conformation. Indeed, most ITAFs possess multiple RNA-binding domains and are able to dimerize in solution. Realization of these multiple RNA-protein and protein-protein interactions could alter the secondary and tertiary structures of IRESs and facilitate their interaction with the canonical translation components. Further information on RNA-binding proteins with their assigned ITAF's function can be found in (King *et al.*, 2010).

Cellular mRNA IRESs

Evidence for cellular mRNA IRESs

In many physiological and pathological situations, such as mitosis, differentiation, apoptosis, stress (e.g., hypoxia or heat

shock), and viral infection, cap-dependent initiation is compromised, either because of cleavage of the canonical eIFs or a change in the phosphorylation state of eIFs and their binding partners (Holcik and Sonenberg, 2005). IRESs were predicted to exist in a subset of cellular mRNAs whose translation is either maintained or enhanced under the conditions of global protein synthesis inhibition (Hellen and Sarnow, 2001).

The structural features of cellular mRNAs that indicate the existence of IRESs are long and extensively structured 5' UTRs and the presence of AUG triplets within 5' UTRs (which is generally incompatible with efficient scanning). The mRNA encoding BiP (immunoglobulin heavy-chain-binding protein) was first suggested to possess IRES because it is translated in spite of the shutoff of cap-dependent translation after PV infection (Macejak and Sarnow, 1991). Since then, more than hundred cellular mRNAs were reported to contain IRESs (up to 10% of all mRNAs, as suggested by *in silico* analyses) (King *et al.*, 2010; Mokrejs *et al.*, 2010). Proteins encoded by mRNAs possessing putative IRESs are often involved in control of cell growth or cell death (Table 2).

Cellular mRNA IRESs are not amenable to classification because of significant difference in sequence and predicted secondary structure (Baird *et al.*, 2006). In contrast to viral IRESs, whose activity is dependent on the integrity of the structural elements, cellular mRNA IRESs are not defined by overall structure, but instead contain several modules that display IRES activities on their own (Baird *et al.*, 2007).

Similar to Type 1 and 2 viral IRESs, activity of cellular mRNA IRESs generally requires all the canonical eIFs, except for eIF4E. Consistent with this presumption, efficient IRES-mediated translation of vascular endothelial growth factor (VEGF) and p120 catenin mRNAs in some breast cancer cell lines correlates with a high expression of eIF4G relative to eIF4E (Silvera *et al.*, 2009).

Activities of putative cellular mRNA IRESs also appear to be dependent on ITAFs, such as PTB, PCBP2, Unr, La, hnRNPA1 and other hnRNPs (Komar and Hatzoglou, 2005; Baird *et al.*, 2006). For example, La has been reported to activate the IRES of laminin B1 mRNA during epithelial to mesenchymal transition of hepatocellular carcinoma cells (Petz *et al.*, 2011). The list of ITAFs specific for cellular mRNA IRESs is steadily growing (King *et al.*, 2010).

As for viral IRESs, the mechanism of activation of cellular mRNA IRES by ITAFs is not known. In some cases, ITAF binding was found to destabilize certain structures within IRESs, which could be inhibitory for the recruitment of ribosomes or other factors (Mitchell *et al.*, 2003). There are also precedents of negative regulation of IRESs by ITAFs (King *et al.*, 2010).

It is noteworthy that many ITAFs shuttle between the nucleus and the cytoplasm. Changes in subcellular distribution of ITAFs under different physiological conditions can provide an important means to regulate IRES-mediated translation (Lewis and Holcik, 2008).

Critical analysis of cellular mRNA IRESs

All cellular mRNAs contain m⁷G-cap at their 5' end and therefore can be translated by the canonical cap-dependent mechanism. Although long and extensively structured 5' UTRs generally inhibit scanning, they are not incompatible with the

Table 2 Examples of cellular mRNAs reported to contain IRESs

cap-dependent translation at least in some cases. It is therefore uncertain whether the IRES-mediated translation of a subset of cellular mRNAs can occur in parallel with cap-dependent scanning and even predominate over the latter mechanism in some circumstances.

First, it could be argued that the affinity of eIF4F for the 5'-end is not the same for all mRNAs. Thus, partial eIF4F inactivation under stress conditions while inhibiting the translation of bulk mRNAs could confer competitive advantage to select mRNAs that have higher affinity for eIF4F (Jackson, 2013). In addition, ribosome shunting, in which ribosomes reach the initiator AUG by bypassing large segments of the 5' UTR, is expected to be favored over scanning when eIF4F activity is reduced (Yueh and Schneider, 1996). Finally, the 'cap- and IRES-independent' scanning mechanism of translation initiation, in which scanning from the 5' end relies on the

interaction of eIF4F with specialized RNA structures called cap-independent translation enhancers, akin to initiation on some plant viral mRNAs, can potentially operate under conditions in which general protein synthesis is inhibited (Shatsky *et al.*, 2010).

With these multiple possibilities of translational persistence of select mRNAs under stress conditions, the question arises of whether initiation via cellular mRNA IRESs is of any physiological significance. Indeed, most of the evidence for activity of cellular mRNA IRESs rests on the method of bicistronic DNA constructs, which could be prone to misinterpretation (Jackson, 2013). In this assay, a fraction of monocistronic mRNAs could be transcribed from cryptic promoters within candidate IRES segments or even within vector backbones if the putative IRESs possess 3'-splice sites (Van Eden *et al.*, 2004; Baranick *et al.*, 2008; Lemp *et al.*, 2012). Common tests to detect monocistronic mRNAs, such as Northern blotting and qPCR, are not always adequate, as they do not provide sufficient sensitivity. A more rigorous test is to co-express a siRNA that targets the first cistron coding sequence (Van Eden *et al.*, 2004). If the siRNA causes no reduction in the second cistron expression, the most likely scenario is that this expression is driven by unintended monocistronic mRNAs. Reevaluation of several cellular mRNAs 5' UTRs by this and other stringent tests failed to confirm the presence of IRESs. To circumvent the above problems, some researches use RNA transfection or *in vitro* translation assays. However, many putative cellular mRNA IRESs appear to be much less active than their viral counterparts in these assays (Shatsky *et al.*, 2010).

Conclusion and Perspective

Since the original discovery of IRESs in picornaviruses (Jang *et al.*, 1988; Pelletier and Sonenberg, 1988), the cap- and 5'-end-independent mechanism of translational initiation has gained significant support in numerous publications. This alternative pathway of translation initiation has apparently evolved to ensure synthesis of select proteins under stress and other physiological and pathological conditions where cap-dependent initiation of translation is inhibited. Deregulation of IRESs occurs in diseases, as putative IRESs are present in mRNAs that encode oncogenes, growth factors, and regulators of apoptosis. Many viruses of significant medical importance use IRESs to synthesize their proteins. These IRESs exhibit a wide diversity with respect to their structure and eIFs requirements. Accordingly, viral IRESs and their ITAFs represent potential targets for the development of novel antiviral therapeutics. Finally, IRESs have emerged as biotechnology tools, in particular for gene therapy, as they function under variable physiological conditions and provide a unique means for co-expression of several proteins from one polycistronic mRNA.

Targeted mRNA Degradation

Introduction

The central dogma of molecular biology postulates the flow of genetic information from DNA to RNA to protein. This implies that gene expression in cells is a multistep process that involves transcription of genetic material from DNA to RNA molecules, followed by translation of messenger RNAs (mRNAs) into proteins. These processes define normal cell states and they are subject to stringent control at all levels – essentially any step of gene expression can be controlled. Generally, the amount of mRNA in a system is tightly regulated by altering its rate of transcription; however, post-transcriptional control mechanisms fine tune amounts of both mRNA and protein through modification, stability, and degradation of these molecules. Historically, gene regulation has been mainly studied from transcriptional regulation point of view; however, recent genome wide analyses of mRNA and protein abundance in mammalian cells (Rabani *et al.*, 2011; Schwanhauser *et al.*, 2011) revealed that posttranscriptional control plays an equally important part during gene expression regulation. While changes in transcription rates indeed determine the majority of temporal changes in mRNA levels, changes in mRNA degradation rates are found to be important for shaping the dynamic nature of gene regulation which is critical for cell proliferation, cell differentiation, stress, metabolism, immune response, and apoptosis (Ghosh *et al.*, 2010; Houseley and Tollervey, 2009; Schoenberg and Maquat, 2012; Wang *et al.*, 2002). Thus, it comes as no surprise that many cellular factors and mechanisms are employed to specifically regulate and modulate mRNA degradation rates.

mRNA stability in eukaryotic cells depends on the presence of a 5' 7-methylguanosine cap (m7G) and 3' poly(A) tail, which both serve as integral stability factors for each transcript. These structures also ensure efficient translation of mRNAs through interactions with translation initiation machinery and poly(A)-binding protein (PABP). Loss of these terminal structures from mRNAs through decapping or deadenylation results in their destabilization. mRNAs lacking a m7G cap are rapidly degraded by the exoribonuclease activity of Xrn1 in the 5'→3' direction. Transcripts lacking a poly(A) tail are eliminated by the 3'→5' exonucleolytic activity of a large protein complex – exosome. These processes serve as the major pathway by which mRNAs are degraded (Figure 1). We note that initial destabilization by decapping and deadenylation is subject to additional regulation by sequence-specific RNA-binding proteins (RBPs), short RNAs, and by RNA secondary structure, making the process of mRNA degradation specific for each individual transcript.

It is worth noting that generation of mRNA through the course of transcription and RNA processing is an imperfect process resulting in a substantial amount of defective transcripts. Furthermore, mRNA is subject to a number of chemical and environmental insults that alter its chemical properties. These mRNAs are subject to quality control processes and

interestingly their decay appears to be initiated through endonucleolytic cleavage. Since the targets of these processes cause mistranslation, it makes great sense that 'mRNA surveillance' depends on the ribosome for the initial recognition of the defect, where the processes are intimately coupled to translation (Shoemaker and Green, 2012).

mRNA Surveillance Mechanisms

As discussed earlier, aberrant mRNAs are generated through multiple pathways. The translation of these defective mRNAs is likely to result in aberrant proteins that are likely to misfold and hence cause havoc on the cell. It is not surprising then that cells evolved a number of quality control processes to recognize and degrade aberrant transcripts from the cellular mRNA pool. In eukaryotes, three cytoplasmic quality control processes have so far been identified (Graille and Seraphin, 2012; Kervestin and Jacobson, 2012; Shoemaker and Green, 2012). These are collectively referred to as 'mRNA surveillance' and include nonsense-mediated decay (NMD), no-go decay (NGD), and nonstop-decay (NSD) (Figure 2). In NMD, transcripts that contain a premature stop codon (PTC) that could result from mis-splicing, for example, are rapidly degraded. The process of NGD is responsible for degrading transcripts that cause stalling during translation. Finally, NSD acts on mRNAs lacking a stop codon where the ribosome runs to the 3'-end of the mRNA.

Substrate Choice

NMD

The process of NMD was initially documented in *Saccharomyces cerevisiae* more than three decades ago, where nonsense mutations in the *URA3* gene were found to have profound effects on the stability of its transcript (Losson and Lacroute, 1979). Soon after that, Maquat *et al.* (1981) showed that β -globin mRNA from β -thalassemia patients, which encodes for a truncated ORF, has a significantly shorter half-life relative to non-thalassemic mRNA. As a result of these initial observations and several others, NMD substrates were classically characterized as transcripts harboring PTCs, which can appear as a result of genomic mutations, transcriptional errors, defective DNA rearrangements, or alternative splicing. The latter process appears to generate many NMD substrates. In particular, it has been estimated that more than 75% of the human pre-mRNA is alternatively spliced and 45% of these produce one mRNA isoform that looks like an NMD target (Lewis *et al.*, 2003).

Recent high-throughput transcriptomic analysis, however, suggests that depending on the organism and conditions, 3–15% of the cellular mRNA pool is subject to NMD (Guan

Figure 1 The main pathways of mRNA degradation in eukaryotes: (a) The canonical degradation pathway. The mRNA is initially deadenylated by the action of a deadenylase complex followed by decapping. The mRNA is then degraded through the action of the 5'–3' exonuclease Xrn1 and the exosome in the 3'–5' direction. (b) Degradation of mRNA through endonucleolytic cleavage. The cleavage creates substrates for the exosome, which degrades the 5' fragment, and Xrn1, which degrades the 3' fragment.

et al., 2006; He *et al.*, 2003; Lelivelt and Culbertson, 1999; Tani *et al.*, 2012). Furthermore, these NMD targets appear to vary from one cell type to another (Huang *et al.*, 2011; Yepiskoposyan *et al.*, 2011). These findings suggest that NMD, in addition to its role in clearing aberrant mRNA, plays a critical role in gene expression and regulation and appears to be important for a wide range of biological problems. Indeed, whereas NMD is dispensable in some lower eukaryotes such as *S. cerevisiae* and *Caenorhabditis elegans*, it is absolutely essential in mammals, zebra fish, and fruit fly. In mice, for example, the absence of NMD causes embryonic lethality (Medghalchi *et al.*, 2001).

These high-throughput studies and the observation that NMD is involved in a number of biological processes indicate that the classical definition of an NMD target as a PTC-harboring transcript is limited. Emerging from these studies is the discovery that many classes of transcripts can trigger NMD. Transcripts having upstream open reading frames (uORF) are logical targets, where a ribosome translating the uORF encounters that looks like a PTC. 3'-UTRs that have an intron also trigger NMD. Furthermore, long UTR, that are present under normal conditions or result from alternative polyadenylation, can trigger NMD (Chen *et al.*, 2006; Martins *et al.*, 2012), however, not all transcripts with long 3'-UTRs do. Collectively these studies suggest that sequence elements downstream of the stop codon, however, are responsible for triggering NMD. This unifying theme is often referred to as the 'faux 3'-UTR' model (Amrani *et al.*, 2004).

NGD

Similar to NMD, NGD was also initially observed in *S. cerevisiae*; Doma and Parker (2006) showed that mRNAs with strong secondary structures such as hairpins, pseudoknots as well as GC-rich sequences are turned over rapidly. These structures cause translating ribosomes to stall, 'not go.' While transcripts containing these roadblocks are the most effective NGD targets, the process appears to have other subtle targets that have features that can modulate the speed of the translating ribosome; these include transcripts harboring strings of rare codons or transcripts coding for peptides that, through interactions with the exit tunnel, stall the ribosome (Kuroha *et al.*, 2010; Letzring *et al.*, 2010). It is worth noting that although the use of mRNA reporters with stable secondary structures or long stretches of rare codons have contributed significantly to the dissection of the mechanism of NGD, such mRNAs for the most part do not exist in the transcriptome and hence they have been argued to have limited biological relevance. Recent data suggests that chemically damaged mRNAs, such as oxidized transcripts, are the real targets of NGD. Some of these adducts have been shown to stall the ribosome *in vitro* (Simms *et al.*, 2014).

NSD

As the name suggests, NSD evolved to degrade mRNAs lacking an in-frame stop codon (Frischmeyer *et al.*, 2002; van Hoof *et al.*, 2002). Formally such targets are of two

Figure 2 mRNA surveillance processes. (a) Canonical termination of protein synthesis. The stop codon is recognized by a ternary complex of eRF1, eRF3, and GTP, which promotes peptide release and initiates recycling of the ribosomal subunits. (b) The exon junction complex (EJC) model of nonsense-mediated decay (NMD). A premature stop codon (PTC) is recognized by eRF1 and eRF3, but due to the presence of an EJC downstream of the stop codon, several other interactions occur with the Upf proteins. These interactions appear to be required for the recruitment of several decay factors. (c) The process of no-go decay (NGD). The yeast eRF1, eRF3, homologues Dom34, and Hbs1 (respectively) recognize the stalled ribosome and bind in the A site. They then catalyze the dissociation of the ribosome and stimulate an endonucleolytic cleavage of the mRNA upstream of the ribosome (not shown). (d) PolyA-mediated nonstop-decay (NSD). In the absence of a stop codon, the ribosome runs to the polyA of the mRNA, synthesizing poly-Lys peptide and effectively stalling the ribosome. The process is similar to NGD in that Dom34 and Hbs1 are sometimes involved but in some organisms other factors are also involved (see text).

different types: the first is generated through truncation or endonucleolytic cleavage and as a result during translation the ribosome simply runs to the end of the message; the second is generated from mutation in the genomic sequence or an error during transcription resulting in mRNAs with no stop codon but with polyA tail. For the latter type, it has been speculated that the ribosome would translate the polyA tail synthesizing long poly-Lys peptide (Ito-Harashima *et al.*, 2007). The poly-Lys sequence accumulates an overall large positive charge, which is hypothesized to interact with the negative charge of the phosphodiester backbone of the ribosome exit tunnel and induce stalling. Hence, NSD and NGD are similar processes except for where the initial signal for the degradation along the mRNA originates; for NGD it is in the middle, whereas for NSD it is at the end. Indeed, as we shall see later the processes appear to share many of the factors in higher eukaryotes.

Substrate Recognition

NMD

As mentioned earlier, all NMD targets share the common feature of having a stop codon at a noncanonical position.

Due to the nature of the stop codon translation termination is speculated to be quite distinct from normal termination (Amrani *et al.*, 2004). The exact mechanism by which the ribosome distinguish between a normal stop codon and a PTC is not fully understood, but it involves three conserved proteins: Upf1, Upf2, and Upf3 in *S. cerevisiae* (Cui *et al.*, 1995; Leeds *et al.*, 1991, 1992). These proteins are thought to bridge a connection between downstream signals and the terminating ribosome (Chakrabarti *et al.*, 2011; Chamieh *et al.*, 2008). The connection between the Upf proteins and the ribosome is thought to be stimulatory for NMD, but inhibitory for termination and they compete with connections that are under normal conditions stimulatory for termination.

How do Upf proteins communicate signals to the ribosome? Early studies on NMD suggested that mRNAs harboring a PTC > ~50 nt upstream of exon-exon junction sites triggered a robust NMD response (Nagy and Maquat, 1998; Thermann *et al.*, 1998; Zhang *et al.*, 1998). Later studies showed that during splicing the region just upstream of the exon-exon junction sites is coated with a protein complex fittingly called the exon junction complex (EJC) (Le Hir *et al.*, 2000). During the pioneering round of translation, the EJC complexes are stripped off the mRNA by the ribosome. Given that most of the stop codons reside in the last exon of a gene,

the presence of an EJC complex downstream of a terminating ribosome provides a rational molecular signature for NMD. The core EJC complex is composed of three proteins, eIF4A3, MLN51, and a MAGOH/Y14 heterodimer, which interacts with the C-terminus of the NMD factor Upf3 (Andersen *et al.*, 2006; Bono *et al.*, 2006; Buchwald *et al.*, 2010). Upf3 has orthologues in all examined eukaryotes and consistent with its interaction with the EJC complex it shuttles between the nucleus and cytoplasm (Kim *et al.*, 2001). Upf2 acts as a bridge between Upf3 and Upf1, which in turn interacts with the release factors eRF1 and eRF3 as well as the phosphatidylinositol 3-kinase-related kinase SMG1 (Kashima *et al.*, 2006; Kunz *et al.*, 2006). Among NMD factors, Upf1 is the most conserved factor and is central to the process (Culbertson and Leeds, 2003). Sequence analysis as well as biochemical characterization of the protein revealed that it belongs to the ATP-dependent helicase superfamily (Cheng *et al.*, 2007; Czaplinski *et al.*, 1995). It binds RNA and ATP and uses the energy from ATP hydrolysis to unwind RNA in a 5' to 3' direction. In addition, the protein is subject to cycles of phosphorylation (by SMG1) and dephosphorylation on its unstructured C-terminus and N-terminus region (Grimson *et al.*, 2004; Okada-Katsuhata *et al.*, 2012; Yamashita *et al.*, 2001). On NMD substrates, Upf1–Upf2–Upf3 form a stable complex and it has been suggested that interaction between Upf2 and a cysteine/histidine (CH) rich domain on Upf1 activates the ATPase and helicase activity of Upf1 (Chamieh *et al.*, 2008). In the absence of Upf2, the CH domain of Upf1 interacts with the factor's helicase domain forming a closed conformation that inhibits the unwinding activity of Upf1. In addition to their interaction with the EJC complex, Upf proteins have been shown to interact with translation factors, namely release factors, for which they appear to modulate termination efficiency (Kashima *et al.*, 2006). Stop codon readthrough is significantly more efficient on PTCs relative to normal stop codons (Wang *et al.*, 2001).

What is clear from the many decades of studies on NMD is that the process is intimately coupled to translation termination. Termination of protein synthesis occurs when one of three nearly universal stop codons (UAG, UGA, and UAA) enter the A site of the ribosome. In eukaryotes, termination requires the two release factors eRF1 and eRF3. eRF1 is a tRNA mimic, which binds the A site of the ribosome and recognizes the stop codon. eRF3 is a GTPase and similar to EF1A (Frolova *et al.*, 1996), which binds aa-tRNAs to deliver them to the ribosome during elongation, is thought to form a ternary complex with eRF1 and GTP (Mitkevich *et al.*, 2006). Once on a terminating ribosome, GTP is hydrolyzed, eRF1 undergoes a conformational change allowing the conserved GGQ domain to engage the active site of the ribosome to initiate peptide release. It has also been suggested that eRF3 interacts with polyA-binding protein (Pab1), and that this interaction stimulates peptide release (Kononenko *et al.*, 2010). Following peptide release, the conserved recycling factor ABCE1 binds to eRF1 kicking eRF3 off; subunit dissociation ensues to complete the translation cycle (Pisarev *et al.*, 2010). Based on this relatively short description of termination, it should be apparent that the process is amenable to modulation through differential protein–protein interaction network. Indeed on NMD substrates, as detailed earlier, termination is inhibited due to

what has been suggested as direct competition between the Upf proteins and termination-stimulating factors (Ivanov *et al.*, 2008). In particular, Upf1 has been shown to interact with eRF3, but whether this interaction on its own is sufficient to elicit NMD is debated.

While the EJC model is elegant and appealing, it fails to explain all of the targets of NMD. An increasing number of NMD-targeted mRNAs do not have an intron downstream of a stop codon and as such are predicted not to harbor an EJC complex. Furthermore, NMD is robust in yeast, even though most of the pre-mRNAs are not spliced. It is worth noting that immunoprecipitation of eIF4AIII (a core component of the EJC) followed by deep sequencing suggests that the EJC can be deposited on mRNAs in a sequence-dependent and splicing-independent manner (Sauliere *et al.*, 2012; Singh *et al.*, 2012). So the possibility that the EJC is found on the UTR of mRNAs lacking an intron downstream of the stop codon cannot be ruled out. Furthermore, for all of these noncanonical targets, the mRNAs share the common feature of having a long UTR. The UTR model suggests that Upf1 binds to mRNAs non-specifically and during translation the ribosome actively displaces the factor (Hogg and Goff, 2010). Since the ribosome does not traverse the 3'-UTR, mRNAs with long UTR are expected to have a larger number of Upf1 proteins and hence are subject to NMD. Alternatively, it has been suggested that the polyA tail of mRNAs with long 3'-UTRs is distant from the stop codon, precluding any stimulatory effect PAB1 might have on termination. In contrast, others have argued that in the absence of a downstream EJC complex Upf2 and Upf3 interact with a ribosome-bound Upf1, which on its own is able to sense the efficiency of termination (Stalder and Muehle-mann, 2008). In summary, Upf1 appears to be the primary factor in determining what constitutes an NMD target whatever the initiating signal might be. Future work is needed to clarify the mechanism of the initial recognition of a PTC.

NGD

NGD is triggered by a stalled ribosome and requires the conserved protein Dom34 (or Pelota) and Hbs1. Interestingly, Dom34 and Hbs1 share structural features with eRF1 and eRF3, respectively (Atkinson *et al.*, 2008; Chen *et al.*, 2010). Consistent with these structural similarities, the factors interact with the A site of the ribosome (Becker *et al.*, 2011) but because Dom34 lacks the GGQ domain of eRF1, the complex does not promote peptide release. Instead, *in vitro* biochemical studies showed that the factors promote subunit dissociation (Shoemaker *et al.*, 2010). Moreover, the recycling factor ABCE1 (Rli1 in yeast) plays an important role during this reaction (Shoemaker and Green, 2011).

How does Dom34–Hbs1 complex recognize a stalled ribosome? How does it compete effectively with the ternary complex of EF1–aa-tRNA–GTP that normally binds the A site during elongation? Important clues into this process emerged from recent biochemical characterization showing an inverse correlation between the efficiency of subunit dissociation activity and the length of the mRNA downstream of the P site (Pisareva *et al.*, 2011; Shoemaker and Green, 2011). In particular, Dom34–Hbs1 appears to prefer ribosomal complexes

with little sequence downstream of the P site. Later structural studies showed that this length dependency is bestowed by Hbs1. The factor binds the ribosome in the mRNA entry tunnel and hence can only bind when the mRNA is short (Becker *et al.*, 2011).

NSD

As mentioned earlier, NSD is similar to NGD except that the former involves ribosomes stalling at the end of the mRNA. As a result, the processes proceed in a similar fashion utilizing the same factors. A notable exception is the requirement of Ski7 for NSD in some species of yeast (van Hoof, 2005). The factor is a translational GTPase related to eRF3 and Hbs1. However, in contrast to eRF3 and Hbs1, which have binding partners (eRF1 and Dom34, respectively), no binding partner for Ski7 has been identified. As a result, the mechanism of the recognition of NSD targets in yeast remains poorly understood. It is worth noting that Ski7 interacts with the exosome, thereby linking ribosome recognition of NSD targets to their ultimate degradation (van Hoof *et al.*, 2002).

Substrate Fate

The ultimate fate of the aberrant mRNA, regardless of the process (NMD, NGD, or NSD), is degradation. All of the pathways eventually utilize canonical decay pathways in both directions: 5'–3' Xrn1-mediated and 3'–5' exosome-mediated. Decay of metazoan NMD targets appears to initiate with an endonucleolytic cleavage catalyzed by Smg6 (Eberle *et al.*, 2009; Gatfield and Izaurralde, 2004). Following this cleavage, the 5' and 3' pieces are degraded by the exosome and Xrn1, respectively. Nonetheless, accumulating evidence suggests that alternative and potentially redundant mechanisms exist for clearing NMD targets that do not include endonucleolytic cleavage. For instance, yeast does not have a Smg6 homologue and no cleavage to date has been observed on NMD targets, yet decay is robust in this organism. Furthermore, tethering of the NMD factor Smg7 to mRNAs, in the absence of the endonuclease Smg6, results in fast degradation of the mRNA (Unterholzner and Izaurralde, 2004). Therefore, it has been suggested that decay of NMD targets can also proceed through exonucleolytic routes. The Smg6–Smg7 complex has been shown to recruit decay factors, mainly the deadenylation machinery, to accelerate degradation of NMD targets (Mitchell and Tollervey, 2003; Muhrlad and Parker, 1994).

NSD and NGD targets are subject to endonucleolytic cleavage. The cleavage has been shown to occur upstream of the stalled ribosome. For NSD, the catalytic subunit of the exosome rrp44 (Dis3), which has endonucleolytic and exonucleolytic activities, has been implicated in catalyzing the initial cleavage reaction (Schaeffer *et al.*, 2009; Schaeffer and van Hoof, 2011). For NGD, the endonuclease is yet to be identified, but Dom34–Hbs1 (although unnecessary for the cleavage activity) appears to stimulate the reaction (Tsuboi *et al.*, 2012). In summary, the three mRNA surveillance processes to a large extent exploit similar mechanisms to initiate the decay of their targets. There is a lot to learn about the

process of recognition of the targets and the mechanism of preparing them for degradation.

Targeted mRNA Degradation in Gene Regulation

In the first part we focused on the process of mRNA degradation due to interruptions in translation cycle that ultimately leads to activation of mRNA surveillance mechanisms. However, as we mentioned earlier, each mRNA transcript will have different set of bound RBPs and RNPs and differences in cellular presence of such *trans* regulatory elements will lead toward variation in mRNA degradation rates and differential gene regulation. The changes in mRNA degradation rates due to the targeted binding of *trans* elements as a subject of gene regulation control are described in nearly all cellular pathways from development to oncogenesis (Keene, 2007; Kishore *et al.*, 2010). As such eukaryotic mRNA degradation rates can vary remarkably from transcript to transcript as well as for the same transcript from cell to cell. Cellular modulators of mRNA degradation rates are mainly short RNAs and RBPs. The principle underlying the modulation of mRNA degradation rates by mRNPs involves controlled exposure of mRNA molecules to cellular RNA degradation machineries. This requires either removal of 'stabilizing' RBPs attached to mRNA transcripts and/or recruitment of 'destabilizing' RBPs and short RNAs. The vulnerable 'exposure' of mRNAs to short RNAs and RBPs dictate particular mRNA decay patterns of such mRNPs via direct or indirect interactions with the enzymes controlling mRNA degradation, mRNA deadenylation, or decapping factors (Figure 3).

mRNA Degradation Control by Short RNAs

microRNA (miRNAs) are short (about 21–25 nt long) non-coding RNAs that regulate the translation and degradation rates of mRNAs through nearly perfect complementary binding of target sequences in mRNA 3' untranslated regions (UTRs) (Bartel, 2004). While originally discovered in the nematode *C. elegans* (Lee *et al.*, 1993; Wightman *et al.*, 1993), they are now regarded as one of the key regulators of genes in most metazoans (Lagos-Quintana *et al.*, 2001; Lau *et al.*, 2001; Lee and Ambros, 2001). miRNAs are thought to regulate the expression of target genes by translational repression and targeted mRNA degradation (Bazzini *et al.*, 2012; Bethune *et al.*, 2012; Djuranovic *et al.*, 2012; Eulalio *et al.*, 2009; Guo *et al.*, 2010; Meijer *et al.*, 2013; Figure 3). These two processes are coupled in the living cell and whether the regulatory effects of miRNAs on target genes are the result of the direct induction of mRNA degradation or effects on mRNA decay are the result of an early block in translation initiation, consequentially leading to rapid mRNA degradation still remains elusive (Djuranovic *et al.*, 2011; Fabian *et al.*, 2010). In both cases miRNAs end up MukMuenhancing mRNA target degradation by directing mRNAs to the regular exonucleolytic mRNA decay involving initial deadenylation of the mRNA via the CCR4–POP2–NOT complex (Huntzinger and Izaurralde, 2011; Figure 3). Effects of miRNAs on mRNA target occur through ribonucleoprotein complexes named miRISCs, which at minimum include the

Figure 3 The basic mechanisms controlling mRNA degradation by microRNA (miRNAs) and RNA-binding proteins (RBPs). Recruitment of the mRNA regulators, such as miRNAs or RBPs, triggers either translational repression or direct destabilization of target mRNAs ultimately leading toward mRNA degradation. RBPs and miRISC (miRNA-AGO-GW182 complex) act directly on translation through interaction with translation initiation factors (eIF3, eIF4A, eIF4E, eIF4G) or PABP, preventing active translation of targeted mRNA and exposing it to mRNA degradation machinery. In alternative pathway, RNA regulators directly recruit mRNA destabilization factors, involved in decapping and deadenylation. The removal of the protective structures from either 5' (m⁷Gppp-cap) or 3'-terminus (poly(A)-tail) of target mRNA results in RNA degradation by Xrn1 (5'–3' decay) and the exosome (3'–5' decay).

miRNA, Argonaute (AGO), and GW182 protein (Wilson and Doudna, 2013). The binding of such minimal miRISC complex is sufficient for translational repression which in turn might be sufficient to make mRNA targets 'vulnerable' to mRNA degradation machinery (Djuranovic et al., 2011). Additionally it was also shown that direct interactions of AGO or GW182 proteins with both deadenylation and decapping factors generate more substantial effects on mRNA degradation (Braun et al., 2011). An interesting fact is that targeting of mRNAs by miRNAs often leads to localization of target mRNAs in cytoplasmic foci termed P-bodies which can act as a site for both storage and degradation of target mRNAs (Parker and Sheth, 2007). It is plausible to think that the complexity of miRNA biogenesis (Ha and Kim, 2014), mechanisms of interaction between miRNAs and target mRNAs (Bartel, 2009) as well as existence of different miRISC complexes (Wu et al., 2013) offer numerous possibilities for modulation of miRNA mediated gene regulation and targeted mRNA degradation.

More recently it was shown that piRNAs, another class of short RNAs, may control mRNA degradation patterns in multiple organisms (Gou et al., 2014; Kiuchi et al., 2014; Rouget et al., 2010; Watanabe et al., 2015). piRNAs are known for their function in the repression of transposable elements primarily within the germ line cells, however their function might be also important in regulation of gene expression (Thomson and Lin, 2009). piRNAs in early *Drosophila* embryos affect nanos mRNA deadenylation and degradation through the interplay with both Smaug, an RNA-binding protein, and already mentioned CCR4-POP2-NOT deadenylation complex (Rouget et al., 2010). In a similar manner, interactions of piRNA-silencing complex (piRISC), containing piRNAs and murine PIWI protein (MIWI), and CCR4-CAF1-NOT deadenylase complex in mouse testes controls expression of approximately 5000 genes through targeted mRNA destabilization through CAF1-dependent deadenylation (Gou et al., 2014).

Targeted mRNA Degradation by RBPs

The main feature of RBPs is the presence of at least one RNA-binding domain in their protein sequence (Lunde *et al.*, 2007). One of the best characterized families of RBPs linked to mRNA degradation is the Hu, ELAV proteins (Brennan and Steitz, 2001; Simone and Keene, 2013). This group of proteins specifically interacts with 3' UTRs of mRNA transcripts containing adenylate/uridylylate-rich elements (AREs), *cis*-regulatory sequences linked to mRNA degradation control (Shaw and Kamen, 1986). The addition of ARE elements derived from the human colony stimulating factor 2 (CSF2) gene to the 3' UTR sequences of a stable reporter mRNA, such as β -globin, results in an unstable chimeric transcript. Such experiments demonstrated the importance of these sequence elements in the stability of mRNAs in the cell (Chen and Shyu, 1995; Shaw and Kamen, 1986). The importance of Hu/ELAV proteins and their biological significance is especially highlighted by their function in neurons. Pathological conditions affecting the level of functional Hu/ELAV proteins lead to severe brain damage pathologies that are quite often connected to degenerative neurological disorders following paraneoplastic syndromes (Darnell, 2013; Pascale *et al.*, 2008). Bioinformatic analyses estimated that 5–10% of the human transcriptome contain AREs and appear to be essential in regulating apoptosis, immune response, and intracellular signaling to name a few (Halees *et al.*, 2008). The exact mechanism by which Hu/Elav and other ARE binding proteins lead to a change in mRNA stability are not yet fully resolved. In one particular example, HuR positively regulates the stability of the mRNA transcript of the human eukaryotic translation initiation factor 4E (eIF4E). The process involves direct competition between HuR and yet another ARE binding factor – AUF1 (Topisirovic *et al.*, 2009). AUF1 has been implicated in RNA decay regulation through its binding to eukaryotic initiation factor 4G (eIF4G) and PABP ultimately leading to mRNA destabilization (Lu *et al.*, 2006). Mechanistically, molecular interaction between AUF1, eIF4G, and PABP may lead to the interruption in translation cycle or/and displacement of PABP from poly(A) tail of AUF1 bound transcripts allowing the deadenylase complex access to the mRNA (Sagliocco *et al.*, 2006). Additionally, AUF1 may facilitate degradation of targeted mRNAs by direct recruiting of exosomes to ARE–mRNA complexes (Chen *et al.*, 2001; Torrisani *et al.*, 2007). At a molecular level, by binding to AREs, AUF1 or HuR are likely to alter some local RNA structure, which in turn provides necessary surface area for additional RBPs or RNPs and hence alters mRNA translation and stability (Wilson *et al.*, 2003; Zucconi *et al.*, 2010). Given that majority (57%) of HuR targets are also bound by AUF1, antagonizing effects and competitive binding to AREs between these two RBPs might be relevant for the stability of many mRNA targets (Lal *et al.*, 2004). In addition to already mentioned HuR/ELAV and AUF1, several other RBPs are also known to interact with AU-rich elements. These among others include – tristetraprolin (TTP) (Lai *et al.*, 1999), butyrate response factor-1 (BRF1) (Stoecklin *et al.*, 2002) and KH-type splicing regulatory protein (KSRP) (Gherzi *et al.*, 2004). The KH domains of KSRP are essential for their degradation activity via interaction with deadenylase PARN, decapping factor Dcp2, and exosome subunit Rrp4 (Chou *et al.*, 2006; Gherzi *et al.*, 2004). TTP and

BRF1 interact specifically with exosomes, the deadenylase complex (involving Ccr4), decapping enzymes, and Xrn1 to promote mRNA degradation in P-bodies through a sequential process (Fenger-Gron *et al.*, 2005; Franks and Lykke-Andersen, 2007; Lykke-Andersen and Wagner, 2005).

Other RBP such as Smaug are also important in controlling translation and degradation of targeted mRNAs. Smaug belongs to a family of conserved sterile alpha motif domain containing RBP and all members of this family are thought to be involved in posttranscriptional gene regulation (Aviv *et al.*, 2003). In *Drosophila*, Smaug plays an important role in post-transcriptional regulation of the RNA-binding protein Nanos (Nos) (Chen *et al.*, 2014). Smaug carries out this function by binding Smaug recognition elements (SREs) in the Nos 3' UTR, as well as in other 3' UTRs. This feature is seen across many RBPs since the specificity for target interaction depends on both primary sequence and secondary structure features (Smibert *et al.*, 1996). Beside the effect on translation inhibition, Smaug was later shown to control the stability of targeted mRNAs by recruiting the deadenylase complex CCR4–POP2–NOT (Semotok *et al.*, 2005).

In addition to those mentioned above, several other *cis*-regulatory elements have been related to RNA degradation control. These include U-rich, CU-rich, GC-rich, poly(C), CA-rich, and GU-rich (GRE) elements (Hamilton *et al.*, 2008; Rattenbacher *et al.*, 2010; Stoecklin *et al.*, 2002; You *et al.*, 1992), which are regulated by a wide range of RBPs. Moreover, with a recent delineation of an 'atlas of mammalian mRNA binding proteins' (Castello *et al.*, 2012) which identified more than 300 newly described RBPs and emerging variety of *cis*-regulatory mRNA degradation elements the complex regulatory landscape controlling the fate of mRNA molecules in the cell is still far from being completely explored.

Combined Action of Short RNAs and RBPs

Last but not least, it is plausible that dynamic combination of miRNAs and RBPs that are associated to most mRNAs modulates these two types of RNA regulatory interactions and that the outcome of such interactions affects the mRNA degradation patterns in yet completely novel fashion (Figure 3). It was shown that binding of HuR protein to the 3' UTR of the CAT1 mRNA in human cells attenuates the repressive effects of miR-122 on CAT1 (Bhattacharyya *et al.*, 2006). These experiments were further confirmed using reporter mRNA targets as well as *in vitro* experiments (Kundu *et al.*, 2012) showing that binding of HuR to mRNA transcripts targeted by miRNAs ultimately leads to the dissociation of miRISC from mRNA target. Furthermore, HuR association with miRNA targets can also inhibit miRNA-induced mRNA deadenylation and degradation. The possible mechanistic explanation for antagonizing actions of HuR protein on miRISC targets came from more recent study on another ARE binding protein HuD (Fukao *et al.*, 2014). While miRISC promoted efficient release of eukaryotic initiation factor 4A (eIF4A) from target mRNAs (Fukao *et al.*, 2014) causing translational repression, HuD protein counteracted this miRISC action by stabilizing binding of eIF4A protein to target mRNAs ensuring efficient translation of such transcripts. In some other cases, RBPs can actually

enhance miRNA regulation. For instance, in mammalian cells, the Pumilio RBPs Pum1 and Pum2 promote the regulatory effects of miR-221/miR-222 on the p27 mRNA (Kedde *et al.*, 2010). In regulation of p27 by Pum1 and miR-221/222, Pum1 binds to a stem-loop containing Pumilio recognition element (PRE) and the miR-221/222 target site relaxing the RNA secondary structure and allowing miRNA binding. These interactions are significant, given that p27 downregulation by miR-221/222 is essential for cell proliferation and may also have a central role in the development of cancer (Triboulet and Gregory, 2010). In the case of E2F mRNA it was demonstrated that removal of PREs or depletion of Pum1/2 prevented miRNA regulation of the E2F mRNA. It is currently unknown how Pum1/2 in conjunction with miRNAs regulates E2F transcript translation and stability (Miles *et al.*, 2012). It is possible that binding of Pum1/2 induces RNA structural rearrangements, however these changes would need to affect three different miRNA binding sites over a several hundred base-pair long distance. At the end, these examples are here illustrating the importance of the physical interactions between mRNA, RBPs, and miRISC to achieve efficient gene regulation through the modulation of RNA degradation rates.

Apoptosis, Death as Part of Life

Ancient Egyptians regarded death as an extension of life and not the end of it. In preparation for the 'underworld journey' elaborate funeral ceremonies were planned carefully and considerable resources had to be spent in elements such as the construction of the tomb and more importantly, the coffin. Construction of coffins was commissioned to dedicated craftsmen while the final touch of decoration with texts and paints was the duty of scribes and painters. Likewise, multicellular organisms have evolved intricate mechanisms of programmed cell death and within their own ceremony take the cell for its final underworld journey. In light of their irreversible character, the onset and propagation of cell death programs are tightly regulated by a convoluted circuitry of molecules with limited protein hydrolysis, phosphorylation, and ubiquitination as the main biochemical regulatory mechanisms (Dix *et al.*, 2012; Peng *et al.*, 2011). Once the cell commits to execute a death mechanism progressive morphological changes reduce the entire cell architecture down to small fragments called apoptotic bodies. Currently four major mechanisms of cell death are described in the literature – apoptosis, necrosis, autophagy, and pyroptosis (Fink and Cookson, 2005; Maiuri *et al.*, 2007; Duprez *et al.*, 2009). The most intensively researched mechanism, apoptosis, has seen significant development in the last 20 years and thanks to this we now have greater understanding of its biomedical and biomedical implications.

Control of cell number in multicellular organism is essential, the human body is composed of approximately 10^{14}

cells and if mitosis were to proceed with no cell death, a person 80-year-old would have a gut of 16 km long and 2 ton of bone marrow and lymph nodes (Melino, 2001; Fischer and Schulze-Osthoff, 2005). In the roundworm *Caenorhabditis elegans* an adult hermaphrodite generates 1090 cells and always the same 131 cells undergo apoptosis during development (Lettre and Hengartner, 2006). Given these numbers we must understand apoptosis as a physiological process vital for organismal development, regulation of the immune system, tissue homeostasis, and elimination of damaged or infected cells (Johnson *et al.*, 2000; Portt *et al.*, 2011). In contrast to this, dysregulated apoptosis is strongly implicated in pathological conditions where the balance of cells is altered, such as cancer, AIDS, Parkinson's disease, ischemia, and heart failure (Elmore, 2007; Favaloro *et al.*, 2012).

The Extrinsic Pathway

Activation of apoptosis may occur via the extrinsic or intrinsic pathway (mitochondrial) depending of the initial stimuli (Stennicke and Salvesen, 2000); both of these pathways rely on the activity of proteases known as caspases and the subsequent cleavage of their specific substrates (Portt *et al.*, 2011; Fuentes-Prior and Salvesen, 2004; Figure 1). The extrinsic pathway is mediated by a group of transmembrane death receptors that belong to the tumor necrosis factor receptor-1 (TNFR1) superfamily in which we find TNFR1 itself, CD95/APO-1, TRAIL receptors, and other death receptors (DR) (Chang *et al.*, 2003). After binding to their cognate trimeric ligand these receptors recruit initiator caspase-8 to a

Figure 1 Apoptotic pathway. (a) Activation of the extrinsic pathway is initiated when a death receptor is bound by a death ligand triggering trimerization and recruitment of elements that form the DISC. Recruitment of pro-caspase-8 to the DISC induces its activation via dimerization, in turn caspase-8 cleaves and activates pro-caspase-3 and -7. (b) In the intrinsic pathway intracellular stimuli promote translocation of pro-apoptotic proteins to the mitochondria causing cytochrome c release and apoptosome assembly. The assembled apoptosome activates pro-caspase-9, which in turn can also activate caspase-3 and -7. Ultimately apoptosis execution via the extrinsic or intrinsic pathway dismantles the cell architecture producing small apoptotic bodies cleared phagocytes. (c) List of some intracellular and viral regulators of apoptosis discussed throughout the text.

multiprotein complex, the death-inducing signaling complex (DISC), that also includes the adaptor FAS-associated death domain (FADD) or TNFR-associated death domain (TRADD) (Boatright *et al.*, 2004; McIlwain *et al.*, 2013). Once activated at the DISC caspase-8 cleaves and activates zymogens of the executioner caspases -3, -6, -7 to directly induce death, or the BH3-only protein BID (BH3-interacting domain death agonist) to initiate the intrinsic pathway (McIlwain *et al.*, 2013). The functional significance of caspase-8 and the other components of the DISC in the context of the extrinsic pathway is highlighted in experimental settings and in cancer. Cancerous cells and cells deficient in some of these elements are resistant to apoptosis mediated by the TNFR family of receptors (Chang *et al.*, 2003; van Raam *et al.*, 2013; Eggert *et al.*, 2001).

The Intrinsic Pathway

The intrinsic pathway is fundamentally regulated and centered around the mitochondria (Figure 1). Here elements of the pro-apoptotic and anti-apoptotic machinery that reside either in the cytoplasm or in the mitochondria itself interact to resolve the cell fate (Wang and Youle, 2009). The stimuli required for activation of the intrinsic pathway are far more diverse than those required for activation of the extrinsic pathway and do not rely on receptor/ligand interactions. Some of the triggers include DNA damage, endoplasmic reticulum stress, serum starvation, chemotherapeutic agents, and UV radiation (Tait and Green, 2010; Wang and Youle, 2009). Although the precise details involved in the execution of the intrinsic pathway depend on the specific initial stimuli the following general

model is widely accepted. Prior to caspase activation (the formal initiation of apoptosis) the release of cytochrome c from the mitochondrial intermembrane space drives the assembly of a macromolecular platform termed the apoptosome (Tait and Green, 2010). Upon release from mitochondria cytochrome c interacts with the apoptotic protease-activating factor-1 (Apaf-1) to drive ATP-dependent oligomerization of the two proteins into a wheel-shaped ring (Riedl and Salvesen, 2007; Taylor *et al.*, 2008). In turn oligomerization of Apaf-1 and cytochrome c serve as a scaffold to recruit caspase-9 monomers to induce its dimerization, resulting in a catalytically competent enzyme. Once activated caspase-9 cleaves and activates caspase-3 and caspase-7 to initiate the apoptotic cascade (Riedl and Salvesen, 2007).

Notably, cross talk between the extrinsic and the intrinsic pathways is possible since both share some common elements. Once activated during execution of the extrinsic pathway, caspase-8 cleaves BID into (cBID) that promotes mitochondrial cytochrome c release, assembly of the apoptosome and activation of caspase-9. The subsequent step, as just described, is activation of caspase-3 and -7 by caspase-9 (Tait and Green, 2010). Whether apoptosis is initiated through the intrinsic or the extrinsic pathway, massive morphological changes reduce the cell architecture down to small fragments that in mammals can be removed by phagocytes to avoid undesired immune response: early cell rounding, plasma membrane blebbing, flipping of phospholipids in the cell membrane, internucleosomal DNA cleavage and degradation, nuclear condensation, detachment from the extracellular matrix, and fragmentation into small apoptotic bodies (Taylor *et al.*, 2008).

Of Life and Apoptosis: The Anti-Apoptotic versus Pro-Apoptotic Machinery

In the introduction we describe the apoptotic pathway assuming a free fall to cellular demise but several lines of evidence show that this scenario is further regulated by the existence of positive and negative effectors of apoptosis that control the onset and progression of the pathway. Generally, this may be achieved directly by targeting caspases or indirectly by antagonizing the negative effect of the caspase inhibitors. Next we describe three protein families that constitute the anti-apoptotic and pro-apoptotic machinery: caspases, the B-cell lymphoma-2 (Bcl-2) family, and inhibitors of apoptosis proteins (IAPs). Within the cell at any given time interactions between members of these three families are finely balanced and disruption of this balance may be enough to establish whether the cell enters into a proliferative state or the apoptotic pathway.

Pro-Apoptotic Proteins

Caspases

The central molecular element, and defining characteristic, of apoptosis are the caspases, a family of cysteine proteases that by means of limited proteolysis deliver and execute apoptotic stimuli (Salvesen and Riedl, 2008). The word caspase derives from cysteine-dependent aspartate-specific protease, which illustrates the remarkable specificity of these proteases for aspartic acid in position P1 of the substrate and variable specificity in positions P2, P3, and P4 (Pop and Salvesen, 2009). The catalytic triad that typifies cysteine proteases, Cys-His-X, is unique among caspases as the third residue and is not conserved in all the members of this family. In caspase-8 the third residue is Arg, in caspase-1 is Pro, and Thr in caspase-3, leading to the possibility that only a Cys-His dyad is required for proton shuttling during catalysis (Stennicke and Salvesen, 1999; Watt *et al.*, 1999). The number of caspases varies across organisms, in *C. elegans* there is one, in *Drosophila* there are four, while in mice and humans this number increases to ten and eleven (Yi and Yuan, 2009). However, the original hypothesis that the expansion in caspase number in mice and humans may be related to the role of these proteases out of the cell death framework is falsified when one considers that Cnidaria – the most primitive multicellular animals, have almost as many caspases as humans do (Zmasek *et al.*, 2007). Not all caspases perform an apoptotic function, indeed the first described member of the family that were later to be named caspases is interleukin 1 converting enzyme (ICE) (Cerretti *et al.*, 1992; Morris *et al.*, 1992). In mammals a general classification based on the physiological role distinguishes between the pro-inflammatory and apoptotic subgroups (Salvesen and Ashkenazi, 2011). Pro-inflammatory caspases include caspase-1, -4, and -5 in humans and caspase-1 and -11 in mice. The group of apoptotic caspases is further subdivided into two subgroups: initiators (-2, -8, -9, and -10) and executioners (-3, -6, and -7), importantly caspase-10 is absent in mice and caspase-11 is absent in humans (Pop and Salvesen, 2009; Tyas *et al.*, 2000; McIlwain *et al.*, 2013; Siegel, 2006). A separate classification has been pondered for

caspase-14 since this is neither pro-inflammatory nor apoptotic, instead this caspase participates in cornification, a phase during keratinocyte differentiation. Expression of caspase-14 is restricted to the skin (Van de Craen *et al.*, 1998). How and why caspases have evolved to program such apparently opposing functions as inflammation, skin cornification, and apoptosis is a mystery.

Initiator (apical) caspases and executioner caspases do not possess the same domain organization and this leads to substantial distinctions in the mechanisms of activation and regulation (Fuentes-Prior and Salvesen, 2004). The proximity-induced model introduced in 2003 (Boatright *et al.*, 2003) explains activation of apical caspases. This model postulates that apical caspases exist as monomeric zymogens that are recruited to macromolecular 'activation platforms' for their activation. Zymogens of caspase-8 are recruited to the DISC through their death effector domain (DEDs) and caspase-9 zymogens are recruited to the apoptosome through the caspase activation and recruitment domain (CARD) (Boatright *et al.*, 2003). Once caspase-8 is in complex with the DISC and caspase-9 is in complex with the apoptosome, activation of zymogen monomers to productive enzymes occurs by means of dimerization followed by cleavage at specific aspartate residues. Although caspase activation is frequently associated with cleavage, this event is not essential for the enzymes to attain full catalytic potential (Boatright *et al.*, 2004; Pop *et al.*, 2006).

Executioner caspases-3, -6, and -7 reside in the cytoplasm as inactive dimers where they are processed and activated by executioner caspases-8, -9, and -10. Cleavage of executioner caspases occurs at specific aspartate residues in the inter-subunit linker between the small and large domain. This single cleavage step induces rearrangement of mobile loops that allow formation and stabilization of the productive catalytic state (Pop and Salvesen, 2009).

Of the three executioner caspases, caspase-6 is the least studied and the most studied are caspase-3 and -7. During the biochemical characterization of caspase-3 and -7 the extensive use of synthetic peptides suggests that activity of these caspases is very similar and they may perform redundant roles. This perspective turned out to be reductionist but it was expanded latter after applying experimental approaches that included the combined use of cell-free extracts and immunodepletion assays. Results from these experiments showed that redundancy in the proteins cleaved by each caspase was rather limited as only a few substrates were cleaved by both caspase-3 and caspase-7. It was observed that caspase-3 processed a larger range of substrates implying that this caspase is the most far-reaching during the demolition phase of apoptosis when cell morphology is reduced down to debris (Slee *et al.*, 2001; Walsh *et al.*, 2008).

Caspases can be considered the Rosetta stone in the design of the apoptotic pathway; preincubation of cells with the pan-caspase inhibitor z-VAD-FMK prior to apoptosis stimulation prevents execution of the pathway (Karpnich *et al.*, 2006). Still, a growing number of publications relate caspases with diverse roles apart from those known in cell death. Caspase-1 and -11 regulate inflammation (Degtarev *et al.*, 2003; Kayagaki *et al.*, 2011), caspase-3 is necessary for erythroblast differentiation, and caspase-8 participates in macrophage differentiation (Yi and Yuan, 2009). Paradoxically,

caspase-8 also has a survival role, mice deficient in caspase-8 die during embryonic development (Varfolomeev *et al.*, 1998). Lethality in caspase-8-deficient mice has been attributed to the complex of two proteins that promote uncontrolled necrosis during development: receptor interacting kinase protein-1 and -3 (RIPK-1 and RIPK-3). Integration of biochemical and genetic data concluded that caspase-8 does not only promote apoptosis but is also a negative regulator RIP-1/RIPK-3 (Kaiser *et al.*, 2011). A valid question at this point would be how does a protein well established as a death promoter turn the switch to cell survival? The answer comes from a different molecular entity formed between caspase-8 and the cellular FLICE-like inhibitor protein (FLIP). Association of caspase-8 and FLIP to form a Csp8/FLIP heterodimer produces a protein with distinct enzymatic activity; this heterodimer displays unique kinetic properties and dissimilar substrate specificity as compared with the caspase-8 homodimer (Pop *et al.*, 2011). Biologically the caspase-8/FLIP dimer is essential for suppression of RIPK1/RIPK3-mediated necrosis during embryonic development and in immune cell proliferation (Oberst *et al.*, 2011).

Bcl-2 family

The B-cell lymphoma-2 (Bcl-2) family of proteins comprises three subfamilies associated mainly with controlling mitochondrial apoptosis: the anti-apoptotic, the pro-apoptotic, and the BH3-only proteins. The members of this family are evolutionary related and share some sequence or structural homology with Bcl-2, the founding member of the family (Taylor *et al.*, 2008). Bcl-2 members of the pro-apoptotic and the BH3-only groups may interact synergistically to promote apoptosis although a mechanistic description to explain these observations is far from complete. An appropriate example of this occurs with two pro-apoptotic proteins, BAX and BAK, and the BH3 only protein, BID. Upon cleavage by caspase-8, cBID drives translocation of BAK and/or BAX to the mitochondrial outer membrane where they oligomerize to form pores that induce mitochondrial outer membrane permeabilization (MOMP) (Youle and Strasser, 2008; Moldoveanu *et al.*, 2013). The indispensable role of Bak/Bax is exemplified in cells deficient in both of these factors as these are resistant to multiple apoptotic stimuli such as chemicals (staurosporine, etoposide, thapsigargin, and tunicamycin), physical insults (ultraviolet radiation), and suboptimal growing conditions (growth factor deprivation) (Wei *et al.*, 2001).

The contribution of MOMP to cell death is dual, first supporting apoptosis and second precipitating in the deterioration of mitochondrial physiology that severely compromises cellular function. The primary intended effect of MOMP is the escape of apoptogenic proteins from the mitochondria into the cytoplasm. As we have described cytochrome c stimulates caspase activation through the apoptosome, while other molecules such as the second mitochondria-derived activator of caspase (SMAC) has an indirect role antagonizing the negative effect of caspase inhibitors (Tait and Green, 2010; Ferrer *et al.*, 2012). The secondary contribution of MOMP is less specific, exhibits slower kinetics compared to that of caspase activation, and signifies an irreversible commitment to die as it carries severe damage in the capacity of the mitochondria to generate energy for the cell. The proposed mechanism involves ATP depletion in the mitochondria as well

as impairment of the respiratory function to generate ATP necessary for clonogenic survival (Lartigue *et al.*, 2009; Kushnareva and Newmeyer, 2010). In light of its cleavage by caspase-8 and as a promoter of cytochrome c release to activate caspase-9, BID has been regarded as an element in which the intrinsic and the extrinsic pathways intersect to potentiate the effect of the initial stimulus (Youle and Strasser, 2008).

Other apoptogenic molecules

In the late 1980s shortly before the discovery of the first caspase, Tschoopp described the isolation and characterization of eight proteases contained in the lytic granules of cytotoxic T lymphocytes (Masson and Tschoopp, 1987). These enzymes termed granzymes (Gzms) are produced by diverse populations of T lymphocytes and natural killers cells (NK) to induce death of malignant and virus-infected cells in order to prevent propagation (Lord *et al.*, 2003). Gzms are serine proteases with a catalytic triad formed by His-Ser-Asp, cleavage specificities among the members of the family are different. GzmM cleaves after Met or Leu, GzmC and GzmH are chymotrypsin-like enzymes that cleave after aromatic residues, GzmA cleaves after basic residues and GzmB acts as caspase-like protease that cleaves after Asp (Chowdhury and Lieberman, 2008; Trapani, 2001; Van Damme *et al.*, 2010). GzmB contributes to apoptosis initiation by directly cleaving and activating caspase-3, thus acting as a pseudo-apical caspase. At the same time GzmB may cleave BID that, as previously discussed for caspase-8, produces cBID to induce MOMP resulting in caspase-9 activation (Lord *et al.*, 2003). The role of the other granzymes in inducing cell death is highly debated, and a consensus is yet to arise.

Lipids

The various aspects of apoptosis explained so far rely entirely on proteins as the primary molecular effector, mounting evidence implicates lipids as prominent figures in apoptosis, noteworthy in the context of membranes. For this matter membranes should not be considered as passive witnesses that form barriers to protect the cell or limit compartments with specialized and dedicated cellular functions. Beyond membrane blebbing, a hallmark of apoptosis, mitochondrial membranes participate actively in apoptosis (Fink and Cookson, 2005). Previously, roles for lipids in cell death were proposed even before caspase participation in apoptosis was established but a mechanistic description was scarce (Obeid *et al.*, 1993).

Initial research to address the involvement of lipids in apoptosis proposed that ceramide had a direct role by way of forming stable channels in the mitochondria outer membrane (MOM) hence supporting escape of small apoptogenic proteins from the mitochondria (e.g., cytochrome c) (Siskind *et al.*, 2002, 2006). However, an alternative model emerging from recent work suggests that metabolic intermediates of ceramide provide the appropriate membrane milieu to anchor Bcl-2 proteins BAK and BAX, therefore acting synergistically in promoting their insertion and polymerization (Ganesan *et al.*, 2010; Chipuk *et al.*, 2012). Under this model sphingosine 1-phosphate (S1P), a precursor in the synthesis ceramide, is necessary for BAK activation stimulated by caspase-8-processed BID. In contrast, activation of BAX was observed to require association with hexadecenal (Hex), a molecule produced

from sphingosine, the immediate ceramide precursor (Chipuk *et al.*, 2012). In both cases regulation of BAK/BAX polymerization by lipids had two direct effects: MOMP and cytochrome c release. Consistent with this data the systematic inhibition or overexpression of enzymes that participate in the metabolism of ceramide, S1P, sphingosine, and Hex lead to either sensitization of cells to apoptosis or clonogenic survival.

Anti-Apoptotic Proteins

IAPs

Considering caspases as the directors that orchestrate the symphony of destruction during apoptosis is not unexpected that these proteases are a molecular target for apoptosis control. A direct mode of caspase regulation is through interaction with members of the IAP family. IAPs are characterized by the presence of 1–3 Baculovirus IAP repeat (BIR), a motif of approximately 70 amino acids that mediates protein–protein interactions (Edlich *et al.*, 2011). The first IAP was described in a Baculovirus strain capable of suppressing apoptosis in infected cells (Clem *et al.*, 1991) and this was followed by the identification of cellular IAPs in insects and vertebrates (Oberoi-Khanuja *et al.*, 2013). In addition to BIR repeats several IAPs contain also a RING domain (really interesting new gene) and a ubiquitin-associated (UBA) domain that endows these proteins to participate in cellular processes regulated by ubiquitination including inflammation, immunity, cell migration, and apoptosis (Gyrd-Hansen and Meier, 2010).

Although all human IAPs, of which there are eight, contain at least one BIR domain the X-linked IAP (XIAP) is the only bona fide caspase inhibitor identified to date (Gyrd-Hansen and Meier, 2010; Oberoi-Khanuja *et al.*, 2013). Specifically, the BIR2 domain inhibits caspase-3 and -7 while BIR3 inhibits caspase -9 (Eckelman *et al.*, 2006; Gyrd-Hansen and Meier, 2010). Unexpectedly, two close paralogs of XIAP, the cellular IAP1 and IAP2 (cIAP1 and cIAP2) also bind caspases -3, -7, and -9 but these are at best weak inhibitors of caspase activity. Presumably the lack of inhibitory action in cIAP1 and cIAP2 is due to mutations on critical residues forming the interacting surfaces with caspases (Eckelman and Salvesen, 2006). Currently, described functions for cIAP1 and cIAP2 relate mainly to their RING domain including regulation of tumor cell migration, extending cancer cell survival and paradoxically activation of caspase-1 through the inflammasome (Oberoi *et al.*, 2012; Bertrand *et al.*, 2008; Labbe *et al.*, 2011). The CARD domain is found only in cIAP1 and cIAP2 but is still not well described. A study that combines structural as well as functional data suggests that in cIAP1 the CARD domain regulates RING negatively preventing its activation to suppress both cell proliferation and migration (Lopez *et al.*, 2011).

Since XIAP is the most relevant IAP in the context of apoptosis we will focus our attention to this protein. XIAP is a well-rounded apoptosis regulator that has evolved several domains to counteract cell death in diverse nodes of function. XIAP is composed of three BIR domains (BIR1, BIR2, and BIR3), a UBA domain, and a RING domain (Gyrd-Hansen and Meier, 2010). The BIR1 domain acts as scaffold for the dimerization and activation of TAK1, which in turn activates the I-kappa B kinase complex (IKK). Activation of IKK

culminates in the activation of the NF-kappaB pathway that indirectly antagonizes cell death by promoting cell survival (Lu *et al.*, 2007). Inhibition of caspase-3 and -7 by BIR2 follows a model of two-site interaction that cooperatively contributes to the full inhibitory power of BIR2. An N-terminal segment that extends beyond BIR2 binds to the caspase active site most likely blocking or reducing substrate access. The second point of interaction comprises a surface groove in BIR2 and the N-terminus of the caspase small subunits (Scott *et al.*, 2005). Inhibition by BIR3 follows a different mechanism to that of BIR2; instead of interfering with the catalytic activity, BIR3 prevents caspase-9 activation. The active form of caspase-9 is an obligate homodimer, a state that is maintained by extensive interactions between β -strands in the small subunits (Renatus *et al.*, 2001). BIR3 inhibits caspase-9 by binding to the monomer in the same region that drives dimerization hence blocking the formation of active dimers (Shiozaki *et al.*, 2003).

The Bcl-2 family

The anti-apoptotic subfamily of the Bcl-2 group is small, sequence analysis of the human genome has identified a total of eight proteins including the first and founding member of this family, Bcl-2 (Youle and Strasser, 2008). Bcl-2 was originally identified as an aberrant chromosomal translocation in a patient suffering acute B-cell lymphoma (thereof its name, B-cell lymphoma-2) and was assumed to be an oncogene (Tsujimoto *et al.*, 1984). This assumption was based exclusively on the analogy with the chromosomal translocation of c-myc present in other tumors of B-cells, but the underlying mechanism was yet to be explored. At that time oncogenes were known to mediate cancer only through unregulated cellular proliferation. Subsequent studies found the connection with apoptosis, Bcl-2 functions to block cytochrome c release thus preventing apoptosis and promoting cancer through cell survival and not via cell proliferation (Vaux *et al.*, 1988; Kluck *et al.*, 1997). To play a pro-survival role Bcl-2 and other homologs like Bcl-XL heterodimerize directly with pro-apoptotic family members Bax and Bak to preclude their homoligomerization at the MOM (Michels *et al.*, 2013). By blocking Bax and Bak, Bcl-2 and Bcl-XL prevent MOMP and inhibit downstream signals in the apoptotic program: activation of caspase -9, and caspase-3 and -7. Furthermore after Bax is translocated to the mitochondria Bcl-XL inhibits Bax by promoting its retrotranslocation back to the cytoplasm, thus functioning as a constant downregulator of MOMP (Edlich *et al.*, 2011).

Members of all three subfamilies of Bcl-2 form an interaction network to regulate apoptosis; a BH3-only protein can interact with different pro-apoptotic molecules, and a Bcl-2 pro-survival protein may interact with different BH3-only proteins or different pro-apoptotic proteins (Shamas-Din *et al.*, 2013). The first model to explain the interplay of Bcl-2 proteins to decide the cell's fate was the 'rheostat' model that proposed a quantitative regulation in which the balance between proteins with opposing biological activities would determine if a cell would proliferate or enter in apoptosis (Korsmeyer *et al.*, 1993). The rheostat model was based only on the ratios of Bcl-2/Bax, however as research in the field has progressed more inclusive and comprehensive models have been proposed. Recently the 'unified' model has emerged to

incorporate the interactions of all three subfamilies of Bcl-2 proteins (Llambi *et al.*, 2011). Under this model two 'modes' of interactions are distinguished, in the first mode the pro-survival proteins sequester BH3-only proteins (mode 1) and in the second mode the pro-survival proteins bind activated proteins BAX and BAK (mode 2). During mode 1, sequestration of BH3 only proteins is less efficient to promote MOMP while mode 2 is a more direct and efficient mechanism to prevent MOMP. In addition, the unified model acknowledges from a previous model 'embedded together' the significance of mitochondrial membrane as the focal point where Bcl-2 proteins reach their active conformation to promote apoptosis (Shamas-Din *et al.*, 2013).

The application of biophysical techniques has helped to dissect with great detail the structural basis of the inhibitory interactions between the apoptotic and anti-apoptotic Bcl-2 proteins. A common feature is the formation of a heterodimer in which an amphipathic α -helix from the BH3 domain of the apoptotic protein is inserted into a hydrophobic groove in the anti-apoptotic binding partner. Examples of this include the BH3 domain from Bak that binds to the hydrophobic cleft in Bcl-XL, the BH3 domain from Bad that binds to Bcl-XL, the BH3 domain from Bim that binds to Bcl-XL and the BH3 domain from Bax that binds to Bcl-2 (Sattler *et al.*, 1997; Petros *et al.*, 2000; Liu *et al.*, 2003; Lomonosova *et al.*, 2009; Ku *et al.*, 2011). Binding of the BH3 domain from pro-apoptotic proteins to anti-apoptotic proteins is not seen exclusively in heterodimers of these subfamilies of Bcl-2 proteins. Homoligomerization of Bax or Bak, activation of Bax and Bak by Bim and Bid in order to promote apoptosis require the same structural elements (Moldoveanu *et al.*, 2013). Surprisingly the interaction of Bax with Bcl-XL during Bax retrotranslocation from the mitochondria to cytoplasm seems to involve the membrane anchoring-region of Bcl-XL with the hydrophobic groove of Bax (Todt *et al.*, 2013).

Anti-apoptosis proteins of viral origin

Viruses are one of the greatest successes in parasitic biology, to fulfill their life cycle they replicate and spread their progeny at the expense of the infected cell. To achieve this viruses have evolved a myriad of almost 'intelligent' strategies: evasion of the host's immune system, manipulation of the cell's molecular machinery and control of apoptosis in the infected cell. Undoubtedly, controlling apoptosis until enough progeny has been secured is a powerful survival advantage for the virus (Roulston *et al.*, 1999). Below we will describe briefly some of the molecular strategies employed by viruses to inhibit apoptosis.

During homeostasis apoptosis functions to maintain adequate numbers of T cells, this is mediated by the expression of the death receptor Fas on the surface of the target cell (Kaplan and Sieg, 1998). When Fas ligand binds to the Fas receptor the interaction triggers the extrinsic apoptotic cascade that activates pro-caspase-8 at the DISC (Holler *et al.*, 2000). Upon infection with the herpes simplex virus type 2 (HSV-2) cells are inhibited from expressing the Fas ligand on the surface, thus HSV-2 suppresses Fas ligand-mediated apoptosis in cells bearing the Fas receptor (Sieg *et al.*, 1996). Lower amounts of Fas ligand found on the surface of infected cells do not correlate with reduced mRNA expression or limited protein production but instead the virus seems to disrupt the

intracellular mechanism of ligand transport (Sieg *et al.*, 1996). This mechanism of cell death inhibition is specific for HSV-2 since HSV-1 modulates apoptosis through a different mechanism. Thus far seven genes from HSV-1 have been proposed to exhibit anti-apoptosis activity with U₅₃ being the most certain of all genes identified. During the first 3 h postinfection with HSV-1 cells may undergo apoptosis, nevertheless after this time U₅₃ blocks cytochrome c release and caspase-3 activation. This suggests that U₅₃ prevents apoptosis upstream of mitochondrial signaling (Nguyen and Blaho, 2007).

Blocking cells from embarking in apoptosis may not only potentiate progeny expansion, but also prevent extensive tissue damage to prolong proper organismal functioning, thus increasing the possibility of infecting other individuals. The hepatitis C virus (HCV) is the etiological agent of hepatitis C, a viral infection that causes severe liver damage and chronic infection that can last for 30 years. HCV is observed to block the extrinsic pathway of apoptosis when cells are stimulated with the TNF-related apoptosis-inducing ligand (TRAIL). In addition, when cells are treated with the chemotherapeutic etoposide HCV inhibits the intrinsic pathway, this effect seems to be mediated by blockage of cytochrome c release (Lee *et al.*, 2005). In both instances, the envelope glycoprotein E2 that controls cell entry and fusion is implicated in regulating resistance of cells to die via apoptosis (Lee *et al.*, 2005; Kong *et al.*, 2013).

Another strategy to control apoptosis is common to several viruses and relies on the direct inhibition of caspase activity by serpins (serine protease inhibitors). Serpins are potent inhibitors of serine and cysteine proteases found in all kingdoms, in mammals these proteins regulate clot formation, blood pressure, connective tissue breakdown and hormone transport (Huntington, 2011; Chen *et al.*, 2011). Viruses have engineered serpins to their own advantage; CrmA (cytokine response modifier A) from the cowpox virus inhibits caspase-1, -6, and -8 by two mechanisms. First CrmA forms an irreversible covalent thioacyl intermediate with the active site cysteine effectively trapping the enzyme to prevent catalysis. Second it induces a significant structural change that further renders enzymes catalytically incompetent. Analysis by mass spectrometry and SDS-PAGE show that the complex of CrmA with caspase-1 or -8 undergoes extensive loss of the small caspase subunit p10 (Dobo *et al.*, 2006). As the active forms of caspase-1 and -8 are obligate homodimers of the form (p10p20)₂, disruption of this stoichiometric ratio upon p10 dissociation is a bonus toward viral caspase inhibition and apoptosis control.

Other non-serpin proteins from viruses also inhibit caspases through covalent-intermediates similar to that explained from CrmA. The protein p35 from the cowpox virus inhibits caspase-1, -3, -6, -7, -8, and -10 (Zhou *et al.*, 1998). Inhibition of caspase-8 by p35 involves the formation of a non-cleavable thioester bond that prevents further cycles of catalysis (Xu *et al.*, 2001). Generally during the reaction an activated water molecule hydrolyzes the thioester intermediate to release the cleaved substrate and the free enzyme. However the N-terminus of p35 blocks access of the water molecule to the active site and the thioester intermediate is 'trapped' in catalysis to prevent regeneration of free caspase-8 (Xu *et al.*, 2001).

Anoikis

SM Frisch, West Virginia University, Morgantown, WV, USA

Introduction

Normal epithelial cells detach from their resident extracellular matrices with high frequency. Anoikis, an ancient Greek word meaning 'homelessness,' is the apoptotic response that ensures they are eliminated (Frisch and Francis, 1994; Frisch *et al.*, 2013). This response prevents the translocation of cells with (epi)genetic changes from attaching elsewhere and exploiting their growth/survival advantages or altered differentiation states from harmful effects on their ectopic tissue of residence. Tumor metastasis requires the suppression of anoikis, through mechanisms that are under extensive investigation (Buchheit *et al.*, 2014; Charpentier and Martin, 2013; Paoli *et al.*, 2013; Simpson *et al.*, 2008).

The core machinery – i.e., death-effector mechanism – of anoikis is identical to that of apoptosis in general (Frisch and Screaton, 2001). Thus, anoikis generally depends upon mitochondrial outer membrane permeabilization (MOMP), with release of cytochrome *c* to generate a caspase-9-containing apoptosome that activates effector caspases. Upstream of mitochondria, Bcl-2 family proteins contribute pro-apoptotic and anti-apoptotic roles as with other apoptotic settings, with Mcl-1 perhaps being of exceptional importance in some contexts (Woods *et al.*, 2007). The BH3-only family genes (Bim, Bmf, Bad, Noxa, and Puma) are very responsive to integrin-assisted signal transduction and have therefore been characterized extensively in the context of anoikis, with evidence for cytoskeletal control by direct interaction in some cases (Schmelzle *et al.*, 2007).

The best-characterized signaling pathways that control the core apoptotic machinery in anoikis are the MAP kinases (ERKs, JNK, and p38 MAPK) and the PI3-Kinase/Akt pathway. The latter is of particular interest, because this pathway is highly regulated both by integrin ligation and metabolic nodes such as insulin/IGF receptors. Moreover, Akt programs downstream metabolism through mTOR, thus affecting cell growth, apoptosis, and autophagy (Ng *et al.*, 2012). Focal adhesion kinase (FAK) is a central non-receptor tyrosine kinase that, in complexes with s-src and numerous other components, integrates signals from integrins, growth factor receptors, including those devoted to metabolic regulation such as insulin and IGF (Zhang and Hochwald, 2014; Zheng *et al.*, 2010). FAK is often over-expressed or hyperactive in tumors, and, as such, is a compelling drug target (Zheng *et al.*, 2010). The aberrant expression of activated trkB – a neurotrophin receptor – in certain tumor types of nonneuronal origin can activate survival signaling through PI3K/Akt as well (Geiger and Peeper, 2007). There is additionally, some evidence for a role of death receptors or their interactants such as FAS-associated death domain protein (FADD) or cellular FLICE (FADD-like IL-1 β -converting enzyme)-inhibitory protein (c-FLIP) in controlling anoikis in certain contexts (Mawji *et al.*, 2007).

Superimposed upon these signaling mechanisms is the anoikis-resistance afforded by the oncogenic epithelial-mesenchymal transition (EMT). EMT is thought to be the gene

expression program driving tumor metastasis (even though detecting EMT *in vivo* can be challenging due to its localized, transient, and reversible properties). Anoikis-resistance conferred by EMT recently has been reviewed elsewhere (Frisch *et al.*, 2013). The loss of E-cadherin plays an important role in this process, through the cytoskeletal protein ankyrin-G, altering the localization of critical transcription factors that control cell survival-related target genes (Kumar *et al.*, 2011). Moreover, the EMT-driven loss of epithelial cell polarity complexes also alters anoikis through the highly interconnected Hippo/YAP/TAZ, TGF- β , and Wnt signaling pathways at the transcriptional level (Frisch *et al.*, 2013). The serine-threonine kinase, integrin-linked kinase (ILK), also contributes to EMT and anoikis-resistance in some contexts, through Akt activation (White *et al.*, 2001).

Why Leave?

It is unclear what drives tumor cells to detach and manifest the complex program of metastasis. What was wrong with their primary environment? The intratumoral cellular metabolic challenges described below may offer an explanation, and, importantly, also, their response to these challenges may equip the tumor cell to metastasize, by enabling them to evade anoikis.

The Challenges of Being a Tumor Cell in its Primary Microenvironment

Oncogenic mutations or epigenetic changes in tumor cells, like some university administrators, politicians, or corporate CEOs, confer short-term growth advantages that, however, pose longer-term survival challenges to their institutions.

First, oncogenic changes often endanger cell survival directly, as is famously the case with c-myc over-expression, which, in the absence of compensatory defects in apoptosis genes, will induce apoptosis (as a complex with p14ARF protein) without fail. There are many indirect challenges as well. In light of the poor vasculature of tumors preceding the angiogenic switch, the tumor cell faces deficits in all manner of nutrients, including carbon sources and oxygen, i.e., hypoxia. Rapid proliferation exacerbates these problems, in that the tumor cell must accelerate anabolic processes to keep pace with growing need for lipids, amino acids, and nucleotides. In addition, the stromal microenvironment may be altered by inflammatory responses, as well as by novel factors secreted by the tumor cells, with indirect consequences for tumor growth. Indeed, different regions of the same tumor may face altogether different problems. A successful tumor must develop region-specific adaptations, overall cooperation among the different regions, and, first and foremost, a cellular exit strategy

that involves at least temporary cell survival, i.e., resistance to anoikis.

Interestingly, some of these very challenges provoke EMT, a stable transcriptional program that, by definition, encompasses anoikis-resistance. For example, in the absence of sufficient oxygen, the transcription factor subunit HIF1- α is stabilized. HIF1 induces antioxidant genes to help neutralize the reactive oxygen species (ROS) generation that, paradoxically, accompanies hypoxia (Buchheit *et al.*, 2014). HIF1 also down-regulates mitochondrial biogenesis and respiration. Moreover, HIF1 induces EMT through induction of the transcription factors Twist, Snail, and ZEB1 as well as stimulation of TGF- β signaling (Haase, 2009; Jiang *et al.*, 2011).

Tumor cells also tend to have high ROS levels, presumably a reflection of their hypoxic environment, and they also tend to over-express antioxidant enzymes, presumably to keep the ROS below a lethal threshold concentration.

The emerging paradigm is that tumor cells respond to microenvironmental signals specific to their location within a tumor by metabolic adaptations that may include EMT, invasion and metastasis, that, to be successful, must be accompanied by anoikis-resistance (Taddei *et al.*, 2013).

ROS and Anoikis – A Double-edged Sword?

ROS arise as reaction products from superoxide, generated chiefly from two sources. First, accompanying oxidative phosphorylation in mitochondria, single electrons are transferred from the electron transport chain to oxygen at a substantial frequency (0.1–2%). This process is altered in tumor cells or in normal cells in novel microenvironments, by multiple factors. Indirectly, the facilitated import of glucose and glutamine are the master controllers of most intracellular metabolism, oxidative phosphorylation being no exception. The glucose and glutamine transporter proteins are thus pivotal regulators of not only energy but also redox potential. Interestingly, the glucose transporter 3 (GLUT3) was recently shown to be up-regulated during EMT by the transcription factor ZEB1, with possible implications for anoikis control (Masin *et al.*, 2014). In addition, the activity of pyruvate dehydrogenase (PDH), the branch point between glycolysis (pyruvate) and TCA cycle (acetyl-CoA) is a major regulatory node for oxidative phosphorylation; the enzyme is inhibited by pyruvate dehydrogenase kinases (PDKs) that are, in turn, regulated by adhesion signals, oncogenic signaling pathways and HIF1 (in the case of PDK1) (Cairns *et al.*, 2007; Grassian *et al.*, 2011; Kamarajugadda *et al.*, 2012). Thus, mitochondrial oxidative phosphorylation is both regulated the level of glucose and the branch point enzyme, PDH.

Within the mitochondria, several factors modulate the amount of superoxide that is produced per unit of substrate. One such factor is a particular isoform derived from an alternative promoter of the SHC1 gene, p66Shc protein. P66Shc resides in the mitochondria and generates superoxides in a complex with cytochrome *c* (Giorgio *et al.*, 2005); the role of this protein in anoikis is discussed below. Superimposed on this, it should be noted that individual electron transport components differ greatly in their effects on ROS levels. For example, the experimental knockdown of certain complex I

components of the electron transport chain (GRIM-19, NDUFS-3) induces ROS, as does inhibition of complex I by the diabetes drug metformin (MF), whereas complex III components are required for hypoxia-induced ROS (Guzy *et al.*, 2005; Huang *et al.*, 2007; Skinner *et al.*, 2012). The mitochondrial uncoupling protein family members (UCP1-3) generally protect against ROS generation, thus certain knock-outs actually promote longevity (Mookerjee *et al.*, 2010). Hence, the electron transport chain should be viewed as a complex machine with both positive and negative components with respect to ROS generation. Bcl-2, in addition to controlling MOMP, also regulates redox balance through interactions with mitochondrial membrane proteins (Chong *et al.*, 2014).

Secondly, superoxides are generated at the membrane by the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase (NOX) complexes, related to those of inflammatory/phagocytic cells. Intriguingly, the cytoskeletal regulatory small GTPase Rac and certain protein kinase C isoforms – both responding to integrins, other cell adhesion molecules, growth factor receptors and (in the case of PKC) direct caspase-mediated proteolytic cleavage – are the major activators of most NOX complexes (Lambeth and Neish, 2014). The non-canonical NOX4 is activated by RhoA, also linked to cytoskeleton and cell adhesion (Manickam *et al.*, 2014). The implications of these connections between NOX complexes and cytoskeleton have not been explored.

However they are generated, all cells have multiple mechanisms for neutralizing ROS efficiently. Superoxides generated as above are rapidly converted to hydrogen peroxide and then to water by superoxide dismutases (SODs) and catalase, respectively; other ROS can be neutralized by other mechanisms. The reduced glutathione (GSH) and thioredoxin pools play important roles in neutralizing ROS. Importantly, their maintenance in the reduced state requires the cofactor NADPH, mainly arising from pentose phosphate pathway (PPP) (Lu and Holmgren, 2014; Singh *et al.*, 2012).

ROS As a Mediator of Anoikis

When epithelial cells lose attachment to matrix, GLUTs are diverted from the membrane, causing a loss of PPP activity, and a sharp increase in cellular ROS, owing to the lack of NADPH (Schafer *et al.*, 2009). This cell death appears to be largely caspase-independent, and its exact mechanism is not clear. The authors propose that the burst of ROS subsequent to NADPH decline ultimately induces cell death due to low-energy charge, as ROS also inhibits utilization of the alternative energy source, fatty acids. Interpretation of these studies is somewhat complicated. They report on events that occur 24 h or later after detachment, perhaps reflecting effects of cell death rather than causes; for example, the NOX complex is activated by caspase cleavage of PKC, so the late ROS burst may be a marker of cell death. The lack of detectable caspase activity in this model may result from the oxidative inactivation of the caspases' cysteine active sites by ROS occurring well after the cell has committed to anoikis (Barboudi *et al.*, 2007).

Nevertheless, this study and others clearly demonstrate that ROS arising from glucose deprivation in suspended cells

contributes to cell death. In principle, at least three survival mechanisms may counterbalance this effect: (1) upon matrix detachment, AMP-activated protein kinase (AMPK) is activated (through the liver kinase B1 (STK11)), inhibiting acetyl-CoA carboxylase, and therefore saving precious NADPH (Ng *et al.*, 2012); (2) AMPK activates autophagy, producing metabolites and aiding the effort to restore energy charge (Dunlop and Tee, 2013); and (3) Tumor cells tend to express a splice variant of pyruvate kinase, PKM2, that is potentially inhibited by growth factor receptors such as fibroblast growth factor receptors (FGFR2) as well as by ROS. This inhibition causes a buildup of glycolytic intermediates that ultimately stimulates the PPP, helping to increase NADPH production (Vander Heiden *et al.*, 2011).

Looking further downstream ROS induces apoptosis at the mitochondrial level by peroxidation of the lipid that sequesters cytochrome *c*, cardiolipin, as well as inactivating anti-apoptotic Bcl-2 family proteins (Huttemann *et al.*, 2011). It is unclear, at present, what the source(s) of this ROS actually is (are). Consistent with the pro-apoptotic role of ROS in anoikis, nevertheless, the over-expression of antioxidant genes appears to be functionally significant, in that experimental over-expression of SOD and/or catalase in normal epithelial cells partially protected against detachment-induced death, while the knockdown of these enzymes in breast cancer cell lines promoted this death response (Davison *et al.*, 2013).

Another potential positive link between ROS and anoikis is in p66Shc, noted above to be a mitochondrial ROS-generating protein, although it demonstrates antioxidant properties when cytoplasmically localized in hematopoietic cells. The knockdown of p66Shc potentially protects against anoikis; mutational analysis indicated that the pro-anoikis effect of p66Shc was not mediated by p66Shc's domain for interaction with cytochrome *c*, the best-characterized mechanism for ROS generation (Ma *et al.*, 2007). Nevertheless, p66Shc was proposed to enforce anoikis through RhoA activation (Ma *et al.*, 2007). Speculatively, because RhoA can serve as a NOX4 activator in some contexts, it remains possible that p66Shc enforces anoikis through ROS (Manickam *et al.*, 2014). Interestingly, the suppression of p66Shc expression by the transcription factor Aiolos is a major contributor to lung cancer (Li *et al.*, 2014).

Further support for the tumor suppressive function of ROS – reflecting, in part, its pro-anoikis effect – also derives from the observations about the transcription factor Nrf2 (Jaramillo and Zhang, 2013). Nrf2 is over-expressed in numerous tumor types, correlating with poor prognosis. It transactivates the expression of several PPP genes, thus maintaining NADPH, and also promotes glutathione synthesis as well as SOD and catalase expression. Nrf2 gene expression is induced by various proliferation-stimulating oncogenes including K-ras, B-raf, and myc. In a fascinating demonstration of the power of metabolic alterations, fumarate hydratase mutations lead to papillary renal cell carcinoma by causing the accumulation of malate, which constitutively activates Nrf2 by binding to its sequestration partner, Keap1 (Kinch *et al.*, 2011). Speculatively, the constitutively activated Nrf2 may protect against anoikis via transactivation of antioxidant genes.

In summary, the evidence presented above strongly implicates ROS as promoters of anoikis that, as such, protect the

organism against tumor metastasis. The concepts in this section are summarized in Figure 1.

ROS as Cell Survival Factors

Most tumors are thought to have elevated ROS levels (Liou and Storz, 2010). These studies are based, however, on comparisons of tumor tissue versus normal tissue. At least in the case of breast cancer, such comparisons are perilous because the tumor tissue is predominantly epithelial whereas the normal tissue is primarily stromal, thus differential gene expression may be attributed to cell type rather than normal versus tumor status. Thus, this conclusion should not be accepted as dogma without further investigation.

Paradoxically, the complete pharmacologic ablation of ROS causes cell cycle arrest or, in some circumstances, may even trigger apoptosis (Giannoni *et al.*, 2008). This is not surprising, in light of several considerations. First, protein tyrosine phosphatases (PTPs) are uniformly and irreversibly inhibited by ROS, due to their uniquely sensitive active sites. PTP activity, therefore, is critically regulated by physiologic ROS levels, with too little leading to global PTP hyperactivation and, consequently, global inhibition of signaling pathways that depend upon tyrosine phosphorylation (Giannoni *et al.*, 2008). Additionally, the hub-like tyrosine kinase c-src is actually activated by ROS by relief of autoinhibition (Giannoni and Chiarugi, 2014). Among other problems, activated src can cause ligand-independent activation of epidermal growth factor receptor (EGFR) and its attendant cell survival signaling. Moreover, many growth factor receptors stimulate NOX complexes to produce superoxides, presumably to attenuate the opposing action of PTPs.

A recent study (Zhu *et al.*, 2011) has proposed that integrins stimulated by the matrix protein angiopoietin-like 4 (ANGPTL4) stimulate the NOX complex to generate ROS in attached cells, activating src and promoting cell survival of attached cells; exogenous ANGPTL4 was found to protect against anoikis in detached cells, accordingly. Neutralization of ROS promoted anoikis, by the criterion of short-term caspase activation after detachment. The apparent contradiction this poses may be reconciled by the specificity of the assay used in the ANGPTL4 study, which, unlike other studies measuring total oxidation potential, was specific for superoxides. Another discrepancy may arise from short-term caspase activity assays in this study versus long-term survival assays in other studies: the former may be more influenced by ROS-mediated caspase inhibition by oxidation.

Several reports have also ascribed an indirect protective role of ROS: its purported ability to induce EMT, through, in part, activation of at least two EMT-driving transcription factors, HIF1 and NF- κ B (Cannito *et al.*, 2008; Cichon and Radisky, 2014). For example, matrix metalloproteases-2 and -9 can cleave the ectodomain of E-cadherin, inducing the expression of a Rac1 isoform, Rac1b, that activates ROS generation through NOX complexes (Radisky *et al.*, 2005). In another example, knockdown of the mitochondrial complex I subunits generates mitochondrial ROS, as mentioned above, which leads the knockdown cell lines to eventually display an EMT phenotype. Persistent activation may in certain contexts lead

Figure 1 Control of anoikis through ROS. Factors that are known to be regulated by cell-matrix adhesion are in blue font. High levels of ROS are generated by cell-matrix detachment and commit the normal detached cell to die. Low levels of ROS (as compared with experimentally induced absence of ROS) may promote cell survival through Src activation and phosphatase inactivation (not shown in figure). ROS is generated in mitochondria during oxidative phosphorylation and also through the action of NADPH (NOX) complexes at the membrane. NOX complexes are usually activated by Rac-GTP, but NOX4 is activated by Rho-GTP. P66Shc may potentially promote ROS generation at mitochondria through an electron transfer reaction with cytochrome *c*, or at the membrane through activation of RhoA/NOX4. The Uncoupling Protein family (UCP) attenuates ROS production. The branch point between glycolysis and mitochondrial respiration is the enzyme PDH, which is negatively regulated by the adhesion-controlled kinases PDKs; thus, PDK may affect the level of ROS generated by mitochondria. In normal, attached cells, ROS levels are kept in check through growth factor-activated glucose transport, which, in addition to providing energy charge, also maintains high levels of NADPH (through the PPP); NADPH is a cofactor for reduced glutathione synthesis. At the transcriptional level, ROS activates at least two transcription factors, HIF1 and Nrf2. HIF1 induces antioxidant and EMT-related gene expression, while repressing mitochondrial biogenesis. Nrf2 also induces a battery of antioxidant genes. Both factors contribute to tumorigenesis and may do so through evasion of anoikis.

to an EMT phenotype that includes transcriptionally programmed anoikis-resistance. It is unclear from these reports, however, whether ROS directly induced a stable EMT phenotype, as opposed to selecting for EMT cells that are resistant to the toxic effects of ROS. Both models have important implications, however, for tumor evolution.

What Otto Warburg Said, How It Was Misinterpreted, and the Idea of Metabolic Coupling in Tumors

Otto Warburg stated that ‘tumor cells’ (an impossible oversimplification) continued to rely on glycolysis even under aerobic conditions that would normally suppress glycolysis. This generalization has not, however, stood the test of time. Moreover, it has been widely misinterpreted to mean that tumor cells uniformly suppress oxidative phosphorylation. As clarified in recent reviews, tumor cells vary dramatically in their relative dependence upon the two metabolic pathways (Dang, 2010; Koppenol *et al.*, 2011). In fact, a single tumor possesses great variation from one region to another, or between primary microenvironment, circulating tumor cell

environment and metastatic niche (Sonveaux *et al.*, 2008). Thus, a single tumor may contain highly oxidative as well as glycolytic regions. The profile of individual tumor cells may well depend upon their availability of oxygen concentration, nutrients, factors secreted by their neighboring stromal cells, and degree of infiltration with immune cells. In fact, the success of an individual tumor cell may well depend on its metabolic plasticity rather than its particular profile at a given time point (Taddei *et al.*, 2013). In this connection, an intimate connection between tumor and stroma, known as ‘metabolic coupling’ (Martinez-Outschoorn *et al.*, 2011) posits that cancer associated fibroblasts – under the influence of secreted factors from the tumor cells – generally operate glycolytically and therefore produce a large quantity of pyruvate and lactate. These metabolites are transported by the monocarboxylate transporter (MCT) family proteins that tend to be over-expressed in aggressive tumors, where they are used primarily in the TCA cycle to produce both metabolites for anabolic processes and energy through oxidative phosphorylation.

What are the implications of this important, emerging model for anoikis regulation? Tumor cells coupled in this way with their neighboring stroma are essentially addicted to

lactate and related monocarboxylic acids as fuel. They are unlikely to utilize the PPP efficiently, thus weakening their NADPH defense and increasing ROS. One of two scenarios may be envisioned. First, EMT is more likely to occur in the presence of increased ROS, via activation of, for example, HIF1 and NF- κ B. EMT will promote both increased invasion and anoikis-resistance, at the transcriptional level. Alternatively, this micro-environment will provide selective pressure for the outgrowth of cells that have a strong antioxidant enzyme-based defense, for example, expression of SOD, catalase. Over-expression of these enzymes protects these cells against anoikis. Thus, metabolic coupling is predicted to drive tumor evolution to generate anoikis-resistant and potentially metastatic cells. This view is supported by emerging concepts that link tumor cell reliance on mitochondrial oxidative phosphorylation with anoikis-resistance. Tumor cells that use lactate as a carbon source, and are therefore obligated to use oxidative phosphorylation, are poorly adapted to the hypoxic environment present in the primary tumor. This provides a stimulus for them to metastasize via transient EMT, suspension of anoikis and increased invasiveness. Indeed, metastatic breast cancer cells recovered from lymph nodes or brain frequently have high mitochondrial number and mitochondrial membrane potential (Amoedo *et al.*, 2014; Taddei *et al.*, 2013).

Summary

The metabolic control of anoikis is clearly established from cell culture models; *in vivo* tumor models are much more difficult to analyze from this perspective, because this would require tracing of an individual cell's metabolic profile *in vivo*, and then following that cell's ability to survive and stay in the primary tumor versus its ability to metastasize – not an easy experimental protocol. As a result, most current *in vivo* data correlate overall tumor metabolic profiles with overall tumor growth and/or chemotherapy resistance, rather an obscure way to infer much about anoikis sensitivity. Nevertheless, tumor cells responses to ROS and other metabolites clearly play a critical role in whether they will die by anoikis, and, if so, how long that process will take, i.e., will it occur before seeding a distant site, as required to prevent metastasis? Technical advances will hopefully elucidate these issues more clearly.

Glossary

Caspases Family of cysteine-dependent aspartate-directed proteases involved in apoptosis, differentiation, and inflammatory responses. In the context of apoptosis, these proteases often operate as part of self-amplificatory catalytic cascades resulting in the massive activation of caspase-3, -6, and -7.

Glutamate-ammonia ligase (GLUL) Enzyme that plays an essential role in the metabolism of nitrogen by catalyzing the reversible condensation of glutamate and ammonia to form glutamine.

Glutamate dehydrogenase 1 (GLUD1) Enzyme of the mitochondrial matrix that catalyzes the oxidative deamination of glutamate to α -ketoglutarate and ammonia.

Harlequin mice Experimental mouse strain that expresses reduced amounts of AIF due to a hypomorphic, X-linked recessive mutation in *Aifm1*.

Mitochondrial transmembrane potential ($\Delta\psi_m$) In physiological conditions, respiratory complexes actively extrude protons from the mitochondrial matrix, resulting in an electrochemical gradient that sustains the catalytic activity of the F_1F_0 -ATPase. This corresponds to an electrical potential of approximately -130 mV.

Mitophagy Selective removal of damaged or supernumerary mitochondria by the autophagic machinery.

Reactive oxygen species (ROS) Highly reactive chemical species containing oxygen. The most common ROS of mitochondrial derivation are superoxide anion (O_2^-) and hydrogen peroxide (H_2O_2).

Tumor protein p53 (TP53) Major oncosuppressor protein involved in the control of cell cycle progression, cell death, intermediate metabolism, and redox balance.

Introduction

Mitochondria

Mitochondria – from the ancient Greek *μίτος*/mitos (thread) and *χόνδρος*/chondros (grain) – are double-membraned cytoplasmic organelles that can be found in virtually all eukaryotic cells (Galluzzi *et al.*, 2010, 2012b). Human mitochondria contain multiple copies of a double-stranded, circular DNA molecule of approximately 16.6 kbp, coding for 22 tRNAs, 2 rRNAs, and 13 proteins (Anderson *et al.*, 1981). Notably, all mitochondrial DNA (mtDNA)-encoded macromolecules are employed *in loco* and most mitochondrial proteins are coded by nuclear genes (Elstner *et al.*, 2009). This implies the existence of refined mechanisms of interorganellar crosstalk that ensure the maintenance of cellular homeostasis in physiological conditions as well as in the course of adaptive stress responses (Galluzzi *et al.*, 2012a; Green *et al.*, 2011; Schmidt *et al.*, 2010).

Normally, mitochondria constitute the most prominent source of intracellular adenosine triphosphate (ATP) and the vast majority of eukaryotic cells critically depends on these organelles for survival (Galluzzi *et al.*, 2012b). This central bioenergetic function, i.e., the condensation of adenosine diphosphate (ADP) with inorganic phosphate to generate ATP, is mediated by the so-called F_1F_0 -ATPase, a multiprotein complex embedded in the inner mitochondrial membrane (IMM) (Devenish *et al.*, 2008; Bonora *et al.*, 2015). To this aim, the F_1F_0 -ATPase dissipates in a controlled fashion the

electrochemical gradient built across the IMM by the sequential activity of four other supramolecular entities embedded in the IMM (respiratory complexes I–IV) and two semi-soluble electron shuttles, i.e., coenzyme Q_{10} and cytochrome *c* (CYTC) (Okuno *et al.*, 2011; Stock *et al.*, 1999; Efremov and Sazanov, 2011). This cascade of redox reactions, which is generally known as oxidative phosphorylation (OXPHOS), requires reduced nicotinamide adenine dinucleotide (NADH), operating as an electron donor, and molecular oxygen, acting as a terminal electron acceptor (which results in its reduction into H_2O) (Mitchell, 1961). Mitochondrial NADH is generated by the tricarboxylic acid (TCA) cycle (also known as Krebs cycle), which in turn feeds either on cytosolic pyruvate of glycolytic derivation or on mitochondrial acetyl-CoA produced by the oxidation of fatty acids (β oxidation). Actually, the Krebs cycle is connected to a plethora of catabolic pathways, including those that mediate the degradation of amino acids and nucleosides (Watford, 1991).

Besides constituting the cell's ‘power plants,’ mitochondria not only host several anabolic reactions (including multiple steps of the biosynthesis of heme and iron–sulfur clusters) (Ajioka *et al.*, 2006; Stehling and Lill, 2013), but are also involved in several signal transduction cascades, in particular in the context of stress responses (Galluzzi *et al.*, 2012a; Tait and Green, 2012; Nunnari and Suomalainen, 2012). At least in part, this reflects (1) the intimate crosstalk through which mitochondria and the endoplasmic reticulum (ER) control intracellular Ca^{2+} stores (Kornmann, 2013; Rowland and Voeltz, 2012); (2) the capacity of mitochondria to produce

reactive oxygen species (ROS) (Sena and Chandel, 2012; Murphy, 2009); (3) the strategic position occupied by mitochondria in the control of multiple signaling pathways leading to cell death (Galluzzi *et al.*, 2009b, 2012a; Vandenabeele *et al.*, 2010; Tait and Green, 2010; Kroemer *et al.*, 2007; Vitale *et al.*, 2011), as discussed below.

Regulated Cell Death

In response to harsh conditions (e.g., steep changes in temperature and extreme ionic strengths), cells die in a virtually instantaneous and uncontrollable manner (Kroemer *et al.*, 2009). Such accidental instances of cell death occur very rarely (if ever) in physiopathological scenarios, as these are characterized by relatively mild homeostatic perturbations. In this setting, cells initially respond to alterations of the intracellular or extracellular microenvironment by activating one or more cytoprotective mechanisms aimed at restoring homeostasis (Portt *et al.*, 2011; Green *et al.*, 2011; Kroemer *et al.*, 2010; Fulda *et al.*, 2010; Tait and Green, 2012). If this attempt fails, as it occurs when the triggering stimulus is excessively intense or durable, the cell actively initiates a genetically encoded (hence regulated) program that leads to its own demise (Galluzzi *et al.*, 2007, 2012d). Of note, similar mechanisms of cellular 'suicide' are activated throughout embryonic and post-embryonic development, providing a critical contribution to morphogenesis, as well as continuously in adult life, underlying the maintenance of tissue homeostasis (Taylor *et al.*, 2008; Jacobson *et al.*, 1997; Claveria *et al.*, 2013). These purely physiological instances of regulated cell death are generally referred to as 'programmed,' as they occur independently of exogenous triggers. Of note, regulated cell death (be it programmed or not) can manifest with an incredibly rich panel of morphologies (Vandenabeele *et al.*, 2010; Kroemer and Levine, 2008; Kroemer *et al.*, 2009; Taylor *et al.*, 2008).

For a long time, the phenotypic features of dying cells have been employed to classify the cellular demise into three classes: (1) apoptosis, manifesting with chromatin condensation, nuclear breakdown, cell shrinkage, blebbing, and the formation of discrete, plasma membrane-bound apoptotic corpses; (2) autophagy, involving the massive accumulation of cytoplasmic vacuoles, and (3) necrosis, being defined by the lack of apoptotic and autophagic characteristics (Vandenabeele *et al.*, 2010; Kroemer and Levine, 2008; Kroemer *et al.*, 2009; Taylor *et al.*, 2008). This classification originated from the poor methodological arsenal that was available for the study of cell death until the 1990s (Kepp *et al.*, 2011; Galluzzi *et al.*, 2009a), and fails to take into account important functional aspects. Thus, definitions based on measurable biochemical/molecular parameters are emerging (Galluzzi *et al.*, 2012d). Such a novel taxonomy encompasses (1) two forms of cell death that manifest with apoptotic features, both of which critically rely on caspase activation; and (2) at least three distinct forms of cellular demise exhibiting necrotic features, including necroptosis, which requires receptor-interacting protein kinase 3 (RIPK3) and mixed lineage kinase domain-like (MLKL), mitochondrial permeability transition (MPT)-dependent regulated necrosis, which obligatorily involves peptidylprolyl isomerase F (PPIF, best known as cyclophilin D,

CYPD), and parthanatos, a poly (ADP-ribose) polymerase 1 (PARP1)-dependent variant of cell death (Galluzzi *et al.*, 2012d, 2014a). Moreover, autophagic cell death has been re-defined as a type of cellular demise that critically depends on the molecular machinery for autophagy (Liu *et al.*, 2013; Galluzzi *et al.*, 2012d; Kroemer and Levine, 2008).

Here, we review the signal transduction cascades whereby mitochondria control several instances of cell death, including intrinsic apoptosis, extrinsic apoptosis, MPT-dependent regulated necrosis, and parthanatos. Moreover, we will present the main molecular mechanisms whereby mitochondria get permeabilized to seal the cell death, i.e., mitochondrial outer membrane permeabilization (MOMP) and MPT.

Mitochondrial Control of Regulated Cell Death

Mitochondrial Control of Apoptosis

Intrinsic apoptosis

Intrinsic (also known as mitochondrial) apoptosis can be initiated in response to perturbations of intracellular homeostasis as different as DNA damage, oxidative stress, cytosolic Ca^{2+} overload, dysregulated protein folding, the rupture of lysosomal membranes, and cytoskeletal alterations (Kroemer *et al.*, 2007). Mitochondria play a key regulatory role in this setting as they integrate anti- and pro-apoptotic signals to seal the cellular fate (Tait and Green, 2010; Taylor *et al.*, 2008; Kroemer *et al.*, 2007; Galluzzi *et al.*, 2012a). Thus, while in the course of adaptive responses to stress mitochondrial integrity is actively preserved via multiple mechanisms (Gomes *et al.*, 2011; Rong and Distelhorst, 2008; Rambold *et al.*, 2011), when pro-apoptotic signals predominate over their anti-apoptotic counterparts most mitochondria lose their structural (and hence functional) integrity via either of two intimately intertwined mechanisms, MOMP and MPT (see below) (Brenner and Moulin, 2012; Brenner and Grimm, 2006; Tait and Green, 2010; Kroemer *et al.*, 2007). This is catastrophic for at least two reasons. First, it coincides with the dissipation of the mitochondrial transmembrane potential ($\Delta\psi_m$), which in turn abrogates mitochondrial ATP synthesis (Mitchell, 1961; Okuno *et al.*, 2011; Rambold *et al.*, 2011), blocks the import of several proteins encoded by the nuclear genome (Neupert and Herrmann, 2007; Jin *et al.*, 2010), and impairs mitochondrial ionic homeostasis (Galluzzi *et al.*, 2012d; Kroemer *et al.*, 2007). Second, it allows for the release of potentially cytotoxic proteins that are normally sequestered within the mitochondrial intermembrane space (IMS), including CYTC (Li *et al.*, 1997; Kluck *et al.*, 1997; Liu *et al.*, 1996), apoptosis-inducing factor, mitochondrion-associated, 1 (AIFM1, best known as AIF) (Joza *et al.*, 2001; Susin *et al.*, 1999), endonuclease G (ENDOG) (Van Loo *et al.*, 2001; Li *et al.*, 2001; Parrish *et al.*, 2001), the inhibitor of apoptosis protein (IAP)-binding mitochondrial protein DIABLO (also known as SMAC) (Verhagen *et al.*, 2000; Du *et al.*, 2000), and HtrA serine peptidase 2 (HTRA2, also known as OMI) (Srinivasula *et al.*, 2003; Yang *et al.*, 2003; Martins *et al.*, 2002).

For illustrative purposes, these proteins can be classified into caspase-dependent and caspase-independent cell death effectors (Galluzzi *et al.*, 2012d; Kroemer and Martin, 2005).

As the current tendency is to view apoptosis as a caspase-dependent instance of cell death (irrespective of its morphological manifestations) (Galluzzi *et al.*, 2012d), we will here focus on IMS proteins that promote caspase activation upon release into the cytosol. Of note, most of these proteins (as well as nearly all the upstream regulators and downstream effectors of apoptosis) are evolutionarily conserved (Zhivotovskiy *et al.*, 2009; Arnoult *et al.*, 2001; Yuan, 1996) and mediate key physiological functions (Galluzzi *et al.*, 2012c; Galluzzi *et al.*, 2008a), perhaps suggesting that evolution has assembled the cell death machinery based on available components rather than building new ones.

CYTC, which normally shuttles electrons between respiratory complex III and IV (Ow *et al.*, 2008), is the prototype of mitochondrial caspase activators (Garrido *et al.*, 2006). Indeed, in the presence of deoxyATP, cytosolic CYTC actively assembles an apoptotic peptidase activating factor 1 (APAF1)-containing supramolecular platform that recruits pro-caspase-9 molecules and favors their proximity-induced activation (Twiddy *et al.*, 2004; Cain, 2003; Rodriguez and Lazebnik, 1999; Riedl and Salvesen, 2007). In turn, caspase-9 is capable of setting off an auto-amplificatory cascade (Mondragon *et al.*, 2009; Garrido *et al.*, 2006) resulting in the massive activation of caspase-3, the central executioner of apoptosis (Taylor *et al.*, 2008; Thornberry and Lazebnik, 1998; Janicke *et al.*, 1998), as well as caspase-6 and -7 (at least in some settings) (Walsh *et al.*, 2008; Lakhani *et al.*, 2006; Leblanc *et al.*, 1999). Although the deletion of the CYTC-coding gene is embryonic lethal, a refined genetic strategy has been successfully implemented to study the lethal functions of this protein. This approach confirmed previous results indicating that the apoptotic machinery is essential for the normal development of the central nervous system (Yoshida *et al.*, 1998; Kuida *et al.*, 1996, 1998) yet demonstrated a differential requirement for CYTC and APAF1 in some instances of apoptosis (Green, 2005; Hao *et al.*, 2005).

At odds with CYTC, DIABLO, and HTRA2 operate as indirect activators of caspases, at least in part as they sequester, thereby inhibiting, several members of the baculoviral IAP repeat containing (BIRC) protein family (Verhagen *et al.*, 2007; Wilkinson *et al.*, 2004; Martins *et al.*, 2002; Wu *et al.*, 2000; Verhagen *et al.*, 2000; Du *et al.*, 2000). In addition, HTRA2 catalyzes the proteolytic cleavage of BIRC family members, hence inactivating them in an irreversible fashion (Yang *et al.*, 2003). Of note, while initially BIRC-like proteins were viewed as mere inhibitors of caspases (Scott *et al.*, 2005; Tenev *et al.*, 2005; Shiozaki *et al.*, 2003; Srinivasula *et al.*, 2001), it is now clear that these factors mediate multipronged cytoprotective effects, regulating not only the execution but also the initiation of apoptosis by virtue of their E3 ubiquitin ligase activity (Yang *et al.*, 2014; Hu and Yang, 2003; Li *et al.*, 2002).

Extrinsic apoptosis

Extrinsic apoptosis is invariably initiated by plasma membrane receptors in response to perturbations of the extracellular microenvironment (Galluzzi *et al.*, 2012d; Kroemer *et al.*, 2007). For illustrative purposes, extracellular pro-apoptotic cues can be subdivided into two mutually exclusive groups: 'active' and 'passive' (Mehlen and Bredesen, 2011; Wajant, 2002). The former are conveyed by the so-called 'death

receptors,' which are activated by soluble or plasma membrane-bound agonists (Schutze *et al.*, 2008; Wajant, 2002; Guicciardi and Gores, 2009; Locksley *et al.*, 2001). Conversely, the latter are transduced by the so-called 'dependence receptors,' which emit an apoptotic signal in the absence of their ligands (Mehlen and Bredesen, 2011; Mille *et al.*, 2009; Tauszig-Delamasure *et al.*, 2007). A detailed description of the molecular events taking place at the intracellular tails of death and dependence receptors upon activation goes beyond the scope of this article and can be found in references Schutze *et al.* (2008), Strasser *et al.* (2009), and Mehlen and Bredesen (2011).

In lymphocytes (exemplifying the so-called 'Type I cells'), death receptors such as FAS (also known as CD95) trigger apoptosis via a caspase-8 (or -10)-dependent signal transduction cascade that does not require mitochondria (Ferreira *et al.*, 2012; Scaffidi *et al.*, 1998). Conversely, in hepatocytes (a prototype of 'Type II cells'), FAS is unable to dispatch an efficient pro-apoptotic signal in the absence of MOMP, which is triggered by the caspase-8-dependent cleavage of the BH3-protein BH3 interacting domain death agonist (BID, see below) (Yin *et al.*, 1999; Li *et al.*, 1998; Luo *et al.*, 1998). Of note, the expression levels of the BIRC family member X-linked inhibitor of apoptosis (XIAP) appear to determine the propensity of cells to behave as Type I or Type II cells in response to death receptor activation (Jost *et al.*, 2009). Thus, as Type II cells contain high levels of XIAP, they undergo apoptosis in response to death receptor agonists only when DIABLO and HTRA2 are released by mitochondria upon MOMP (Jost *et al.*, 2009; Kaufmann *et al.*, 2012). This said, the formal distinction between Type I and II extrinsic apoptosis in terms of mitochondrial involvement may be less clear than what thought until recently (Meng *et al.*, 2011; Maas *et al.*, 2010).

The signal transduction cascades linking dependence receptors to apoptosis are heterogeneous and generally do not involve mitochondria (Mehlen and Bredesen, 2011). For instance, while unoccupied unc-5 homolog B (UN5B) triggers apoptosis via a protein phosphatase 2A (PP2A)- and death-associated protein kinase 1 (DAPK1)-dependent mechanism (Guenebeaud *et al.*, 2010), the absence of sonic hedgehog (SHH) endows patched 1 (PTCH1) with the ability to recruit a caspase-9-activatory platform involving the adaptors DRAL and TUCAN (Mille *et al.*, 2009). As an exception, the withdrawal of neurotrophin 3, one of the main ligands of neurotrophic tyrosine kinase, receptor, type 3 (NTRK3, best known as TRKC), results in the generation of a TRKC fragment that is shuttled to mitochondria by negative elongation factor complex member B (NELFB, best known as COBRA1) to promote MOMP (Tauszig-Delamasure *et al.*, 2007; Ichim *et al.*, 2013).

Taken together, these observations indicate that mitochondria play a critical role in the regulation of both intrinsic and extrinsic instances of apoptosis (Figure 1).

Mitochondrial Control of Regulated Necrosis

Initially, mitochondria were thought to play a critical role in all main instances of regulated necrosis described to date, including necroptosis (Wang *et al.*, 2012; Galluzzi *et al.*, 2011;

Figure 1 Mitochondrial control of apoptosis. Mitochondria constitute the central regulator of intrinsic apoptosis and contribute to several instances of its extrinsic counterpart. This key role reflects the dramatic consequences of widespread mitochondrial outer membrane permeabilization (MOMP), including (1) the arrest of ATP synthesis and other mitochondrial transmembrane potential ($\Delta\psi_m$)-dependent activities, and (2) the release of several cytotoxic proteins that are normally sequestered within the mitochondrial IMS into the cytosol. The latter include direct as well as indirect activators of caspases, globally promoting the self-amplificatory caspase (CASP) cascade that underlies the execution of apoptotic cell death. APAF1, apoptotic peptidase activating factor 1; BIRC, baculoviral IAP repeat containing; CYTC, cytochrome c; HTRA2, HtrA serine peptidase 2; IMM, inner mitochondrial membrane; OMM, outer mitochondrial membrane.

Vandenabeele *et al.*, 2010; Zhang *et al.*, 2009), MPT-driven regulated necrosis (Schinzel *et al.*, 2005; Baines *et al.*, 2005; Nakagawa *et al.*, 2005), and parthanatos (Wang *et al.*, 2003, 2011; Yu *et al.*, 2002). While the actual requirement of mitochondria for the execution of necroptosis has nowadays been reconsidered, these organelles are still regarded as key regulators of MPT-driven necrosis and parthanatos (Galluzzi *et al.*, 2014a; Vanden Berghe *et al.*, 2014).

The suspicion that mitochondria could be involved in necroptosis first surged in 2009, when RIPK3 was shown to boost the activity of several mitochondrial enzymes, including glutamate-ammonia ligase (GLUL) and glutamate dehydrogenase 1 (GLUD1) (Zhang *et al.*, 2009). Additional evidence was taken in support of a mitochondrial involvement in necroptosis, including the relatively circumstantial implication of (1) ROS (of unclear origin) (Morgan *et al.*, 2008; Kim *et al.*, 2007; Goossens *et al.*, 1999; Schulze-Osthoff *et al.*, 1992), (2) adenine nucleotide translocase (ANT) inhibition (Temkin *et al.*, 2006), and (3) the accumulation of mitochondriotoxic lipids like ceramide (Kim *et al.*, 2005; Suffys *et al.*, 1991). In that period, the concept of necroptosis had just begun to gather consensus and the molecular mechanisms responsible for this instance of regulated cell death were for the most part unknown (Galluzzi *et al.*, 2011; Vandenabeele *et al.*, 2010). The first connections between RIPK3 and the execution of necroptosis were indeed traced in 2012, when MLKL was suggested to transduce necrotic signals via a phosphoglycerate mutase family member 5 (PGAM5)-dependent, dynamin 1-like (DN1L)-mediated mechanism resulting in mitochondrial fragmentation (Wang *et al.*, 2012; Sun *et al.*, 2012). Since then, the critical function of MLKL in necroptosis has been confirmed and characterized ever more precisely (Galluzzi *et al.*, 2014b; Chen *et al.*, 2014; Cai *et al.*, 2014; Murphy *et al.*, 2013; Wu *et al.*, 2013). On the contrary, the actual implication of PGAM5, DN1L, and mitochondrial fragmentation has remained unconfirmed since. Recently, Douglas Green and collaborators have demonstrated that cells deprived of most mitochondria upon the induction of widespread mitophagy are resistant to apoptotic triggers but perfectly sensitive to the induction of necroptosis (Tait *et al.*, 2013). The same authors have also shown that the absence of (most) mitochondria significantly blunts the production of ROS, yet does not compromise the ability of butylated hydroxyanisole, a ROS scavenger, to rescue cells from necroptosis (Tait *et al.*, 2013). Taken together, these findings indicate that necroptosis does not causally involve mitochondria (and by extension mitochondrial ROS).

Conversely, mitochondria play a critical role in MPT-driven regulated necrosis (Schinzel *et al.*, 2005; Baines *et al.*, 2005; Nakagawa *et al.*, 2005). The term MPT is generally employed to indicate an abrupt increase in the permeability to ions and small solutes of the IMM, resulting in the osmotic breakdown of mitochondria (see below) (Brenner and Moulin, 2012; Brenner and Grimm, 2006). The precise composition of the supramolecular entity that is currently believed to mediate the MPT, the so-called 'permeability transition pore complex' (PTPC), has not yet been determined with precision (Galluzzi and Kroemer, 2007; Baines *et al.*, 2007; Kokoszka *et al.*, 2004). Nonetheless, robust pharmacological and genetic evidence accumulated throughout the past two decades demonstrates

that CYPD controls several instances of MPT-driven regulated necrosis in a nonredundant fashion (Schinzel *et al.*, 2005; Baines *et al.*, 2005; Nakagawa *et al.*, 2005). Thus, rodents pretreated with CYPD inhibitors (e.g., cyclosporin A and sangliferin A) as well as *Ppif*^{-/-} mice appear to be more resistant than their vehicle-treated or wild-type counterparts to a variety of insults that promote necrotic cell death *in vivo*, including ischemia-reperfusion injuries of the heart (Nakagawa *et al.*, 2005; Baines *et al.*, 2005; Kung *et al.*, 2011), brain (Schinzel *et al.*, 2005; Vaseva *et al.*, 2012), and kidneys (Linkermann *et al.*, 2013; Devalaraja-Narashimha *et al.*, 2009).

Of note, in selected instances, MPT-driven cell death can manifest with an apoptotic, rather than a necrotic, morphology (Kroemer *et al.*, 2009; Galluzzi *et al.*, 2007). The reasons underlying such a variability in the morphological manifestations of MPT, possibly reflecting the activation of distinct biochemical cascades, are poorly understood. As caspase-dependent proteolysis is an energy-consuming process and MPT is generally associated with the abrupt cessation of mitochondrial ATP synthesis, intracellular ATP stores have been suggested to entirely determine how MPT-driven cell death is executed (and hence manifests) (Leist *et al.*, 1997). More probably, several different factors influence the propensity of caspases to intervene in MPT-driven cell death, perhaps including the expression levels of BIRC family members and their endogenous inhibitors (Jost *et al.*, 2009). In addition, multiple IMS proteins released by permeabilized mitochondria mediate bona fide caspase-independent cytotoxic functions. This is the case of HTRA2, which degrades many proteins other than BIRC family members (Srinivasula *et al.*, 2003; Yang *et al.*, 2003; Martins *et al.*, 2002), as well as of ENDOG and AIF, both of which can access the nucleus and operate as endonucleases to mediate large-scale chromatin degradation (at least in some circumstances) (Parrish and Xue, 2003; Ye *et al.*, 2002; Van Loo *et al.*, 2001; Li *et al.*, 2001). In summary, mitochondria exert a crucial control on MPT-driven cell death, which most often (but not always) manifests with a necrotic morphotype.

Along similar lines, mitochondria have been critically involved in the execution of the PARP1- and AIF-dependent instance of regulated necrosis known as parthanatos (Wang *et al.*, 2011, 2003; Yu *et al.*, 2002). Interestingly, while *Parp1*^{-/-} mice are viable and develop normally (Masutani *et al.*, 1999; Wang *et al.*, 1995), the lack of *Aifm1* at the whole body level is associated with death by embryonic day E9 (Brown *et al.*, 2006). In addition, the cardiac and skeletal muscle-specific deletion of *Aifm1* results in the gross metabolic perturbations that reflect respiratory defects at the level of complex I (Pospisilik *et al.*, 2007; Joza *et al.*, 2005). Thus, AIF resembles CYTC in that it normally mediates key, non-redundant vital functions (Galluzzi *et al.*, 2008a, 2012c). Nonetheless, a large amount of experimental evidence convincingly links PARP1 hyperactivation to the calpain-independent and PAR-dependent release of AIF from mitochondria and neuronal death *in vivo* (Wang *et al.*, 2009, 2011). Thus, rodents pretreated with chemical inhibitors of PARP1, *Parp1*^{-/-} mice as well as Harlequin mice (Klein *et al.*, 2002), reportedly resist a wide panel of neurotoxic insults including multiple chemicals (Mandir *et al.*, 1999, 2000; Wang *et al.*, 2009), excitotoxic neurotransmitters (Andrabi *et al.*, 2011),

irradiation (Osato *et al.*, 2010), trauma (Piao *et al.*, 2012; Sarnaik *et al.*, 2010), retinal detachment (Hisatomi *et al.*, 2008), as well as perinatal (Hagberg *et al.*, 2004; Zhu *et al.*, 2003, 2007b), and adult cerebral ischemia (Culmsee *et al.*, 2005; Zhu *et al.*, 2007a; Thal *et al.*, 2011; Li *et al.*, 2010).

Besides promoting the release of AIF from mitochondria, a process that depends on the binding of AIF to poly(ADP-ribose) moieties (Wang *et al.*, 2011), PARP1 hyperactivation results in the rapid depletion of NAD⁺, which has a dramatic impact on both mitochondrial and glycolytic ATP synthesis (Chiarugi, 2005). The relative contribution of such a bioenergetic crisis and AIF to the execution of parthanatos remains to be established and may exhibit a significant degree of context dependency. Several factors including global metabolic fitness (Galluzzi *et al.*, 2013) as well as previous exposure to DNA-damaging conditions (Michels *et al.*, 2013) may indeed influence the propensity of cells to undergo parthanatos. Further studies are required to elucidate these aspects.

Irrespective of the above-mentioned incognita, mitochondria play a critical role in the control of MPT-driven regulated necrosis and parthanatos, while they appear to be dispensable for necroptotic cell death (Figure 2).

Mitochondrial Membrane Permeabilization

MOMP

MOMP is the major mechanism whereby mitochondria lose their structural and functional integrity in the course of apoptosis (Tait and Green, 2010; Taylor *et al.*, 2008; Kroemer *et al.*, 2007), and is specifically initiated at the outer mitochondrial membrane (OMM) by the pore-forming activity of multidomain pro-apoptotic members of the Bcl-2 protein family, notably BCL2-associated X protein (BAX) and BCL2-antagonist/killer 1 (BAK1) (Lindsten *et al.*, 2000; Wei *et al.*, 2001). Under physiological conditions, BAX exists as a cytosolic protein, while BAK1 is associated with the OMM in an inactive conformation (Czabotar *et al.*, 2014; Youle and Strasser, 2008; Schellenberg *et al.*, 2013). In response to several triggers, both BAX and BAK1 undergo a conformational shift that confers them the ability to form large, homo- and/or heterodimeric channels across the OMM (Czabotar *et al.*, 2013; Suzuki *et al.*, 2000; Griffiths *et al.*, 1999; Desagher *et al.*, 1999). These pores are generally large enough to allow for the release of soluble IMS proteins into the cytoplasm, *de facto* initiating the assembly of the apoptosome and the execution of apoptotic cell death (Bleicken *et al.*, 2013; Rehm *et al.*, 2003; Kuwana *et al.*, 2002; Antonsson *et al.*, 2000).

The pore-forming activity of BAX and BAK1 is tightly controlled by various other members of the Bcl-2 proteins, including multidomain anti-apoptotic proteins-like B-cell CLL/lymphoma 2 (BCL-2), BCL2-like 1 (BCL2L1, best known as BCL-X_L), and myeloid cell leukemia sequence 1 (MCL1) as well as small, pro-apoptotic BH3-only proteins, including BID, BCL2 binding component 3 (BBC3, best known as PUMA), BCL2-like 11 (BCL2L11, best known as BIM), phorbol-12-myristate-13-acetate-induced protein 1 (PMAIP1, best known as NOXA), and BCL2-associated agonist of cell death (BAD) (Czabotar *et al.*, 2014; Youle and Strasser, 2008; Willis and

Figure 2 Mitochondrial control of regulated necrosis. While necroptosis appears to proceed irrespective of a causal mitochondrial involvement, this is not the case of mitochondrial permeability transition (MPT) driven regulated necrosis and parthanatos, both of which are controlled (at least in part) by mitochondria. MPT can be ignited by oxidative stress or cytosolic Ca^{2+} overload and results in the immediate cessation of mitochondrial transmembrane potential ($\Delta\psi_m$)-dependent functions, including ATP synthesis, as well as in the osmosis-driven structural breakdown of mitochondria. Although MPT involves the release of caspase activators and can indeed elicit apoptosis, in selected circumstances, MPT-driven necrosis is insensitive to caspase inhibition. Thus, other mechanisms are involved in the execution of this cell death subroutine, including the bioenergetic crisis resulting from the abrupt cessation of ATP synthesis and the release of caspase-independent cell death effectors normally sequestered within the mitochondrial intermembrane space (IMS). Parthanatos is elicited in the context of poly (ADP-ribose) polymerase 1 (PARP1) hyperactivation, which also causes major bioenergetic issues as it depletes NAD^+ . In addition, hyperactive PARP1 promotes the selective release of AIF from the IMS, hence unleashing its concealed endonucleolytic activity. ENDOG, endonuclease G; HTRA2, HtrA serine peptidase 2; IMM, inner mitochondrial membrane; OMM, outer mitochondrial membrane.

Adams, 2005). Anti-apoptotic BCL-2-like proteins are localized to the OMM and exert main MOMP-inhibitory functions as they sequester their pore-forming counterparts into inactive complexes (Edlich *et al.*, 2011; Fletcher *et al.*, 2008; Cheng *et al.*, 2003). In addition, BCL-2-like proteins have been shown to mediate cytoprotective effects (1) as they antagonize the activity of BAX and BAK1 at the ER, hence limiting the size of ER Ca^{2+} stores (Oakes *et al.*, 2005; Scorrano *et al.*, 2003), (2) as they promote mitochondrial ATP synthesis by physically interacting with the F_1F_0 -ATPase (Perciavalle *et al.*, 2012; Chen *et al.*, 2011; Alavian *et al.*, 2011).

Conversely, BH3-only proteins generally operate as stress sensors, becoming activated via transcriptional or post-translational mechanisms in response to multiple perturbations of intracellular homeostasis (Llambi *et al.*, 2011; Adams and Cory, 2007). Thus, BID is generally activated upon caspase-8 cleavage, representing the main link between extrinsic and intrinsic apoptosis (Li *et al.*, 1998; Luo *et al.*, 1998; Lovell *et al.*, 2008), PUMA and NOXA are transactivated in response to DNA damage by tumor protein p53 (TP53, best known as p53) (Michalak *et al.*, 2008; Nakano and Vousden, 2001; Yu *et al.*, 2001), BIM is released by inhibitory interactions with cytoskeletal components upon phosphorylation (Chen and Zhou, 2004; Puthalakath *et al.*, 1999), while the pro-apoptotic activity of BAD requires its dephosphorylation (Yan *et al.*, 2013; Kutuk and Letai, 2008). For illustrative purposes, BH3-

only proteins can be classified into two groups based on their main mechanism of action, namely, 'activators' (prototypes: BID, BIM) and 'derepressors' (prototypes: NOXA, BAD) (Kim *et al.*, 2006, 2009; Letai *et al.*, 2002; Giam *et al.*, 2008). Thus, while the former are thought to promote the pore-forming activity of BAX and BAK1 upon direct, though liable, physical interactions, a process that has also been indicated as 'kiss-and-run activation' (Chen *et al.*, 2005; Ren *et al.*, 2010), the latter do so indirectly, by displacing BAX and BAK1 from inhibitory liaisons with BCL-2-like proteins (Chen *et al.*, 2005; Willis *et al.*, 2005). Of note, MOMP as elicited by multiple stimuli (including developmental cues) critically relies on the presence of at least one of the main activator BH3-only proteins BIM, BID, and PUMA (Ren *et al.*, 2010). At odds with previous beliefs, it has recently been suggested that activator BH3-only proteins may exhibit some degree of specificity for BAX or BAK1 and hence exert non overlapping roles (Sarosiek *et al.*, 2013). Moreover, recent findings indicate that BAX is targeted to mitochondria continuously, not only upon activation by BH3-only proteins (Schellenberg *et al.*, 2013). According to this model, MOMP would be normally avoided by the continuative retrotranslocation of BAX to the cytosol, a process that would be mediated by BCL-X_L (Edlich *et al.*, 2011; Schellenberg *et al.*, 2013).

Interestingly a cytosolic pool of p53 has been ascribed with the ability to trigger MOMP in a transcription-independent

Figure 3 Mechanisms of mitochondrial membrane permeabilization. In the course of apoptosis and regulated necrosis, mitochondria can lose their structural and functional integrity via either of two non-mutually exclusive mechanisms, mitochondrial outer membrane permeabilization (MOMP) and mitochondrial permeability transition (MPT). The former is initiated at the outer mitochondrial membrane (OMM), and is controlled by several members of the Bcl-2 protein family. The latter originates at the inner mitochondrial membrane (IMM), owing to the activity of a poorly characterized, cyclophilin D (CYPD)-controlled supramolecular entity known as permeability transition pore complex (PTPC). Interestingly, the molecular machineries for MOMP and MPT mutually interact and are both regulated, via transcriptional as well as posttranslational mechanisms, by p53. Both MOMP and MPT result in the structural breakdown of mitochondria, dictating mostly apoptotic and mostly necrotic instances of cell death, respectively. BAD, BCL2-associated agonist of cell death; BAK1, BCL2-antagonist/killer 1; BAX, BCL2-associated X protein; BCL2, B-cell CLL/lymphoma 2; IMS, intermembrane space.

fashion via multiple mechanisms, including (1) a derepressor BH3-only protein-like activity, resulting in the liberation of BAX and BAK1 from their anti-apoptotic counterparts (Galluzzi *et al.*, 2008; Moll *et al.*, 2005; Mihara *et al.*, 2003); and (2) an activator BH3-only protein function, directly promoting the pore-forming activity of BAX (Chipuk *et al.*, 2003, 2004). The nuclear pool of p53 appears to play a critical role in this latter setting as it transactivates PUMA, hence causing the displacement of cytoplasmic p53 from inhibitory interactions with BCL-X_L and allowing it to mediate full-blown extranuclear apoptotic functions (Chipuk *et al.*, 2005).

Of note, in spite of nearly two decades of studies, the precise mechanisms whereby BAX- and BAK1 mediate MOMP have not yet been determined at the molecular level (Bender and Martinou, 2013; Czabotar *et al.*, 2014). It has been proposed that some mitochondrion-restricted lipids, including cardiolipin (Kuwana *et al.*, 2002; Lutter *et al.*, 2000; Choi *et al.*, 2007), would play a prominent role in this process, yet conclusive evidence in support of this hypothesis is lacking. Along similar lines, although several Bcl-2 proteins have been shown to functionally and physically interact with various components of the molecular machinery that controls

mitochondrial dynamics (Rolland *et al.*, 2009; Berman *et al.*, 2009; Sheridan *et al.*, 2008; Karbowski *et al.*, 2006; Arnoult *et al.*, 2005), to which extent mitochondrial fission and fusion actually influence MOMP remains to be determined, as several contradictory reports have been published in this respect (Van Der Bliek *et al.*, 2013; Martinou and Youle, 2011; Westermann, 2010). Interestingly, recent data suggest that BAX and BAK1 may impact on the propensity of cells to undergo MPT (see below) owing to their ability to regulate mitochondrial dynamics (Whelan *et al.*, 2012). Further studies are required to provide additional insights into this possibility.

Irrespective of these and other unresolved questions, MOMP stands out as a central step in the regulation of apoptosis (Figure 3).

MPT

MPT is a key decisional step in some apoptotic and necrotic instances of cell death (Galluzzi *et al.*, 2012d, 2014a; Kroemer *et al.*, 2007), and – contrarily to MOMP – is specifically initiated at the IMM (Brenner and Moulin, 2012; Brenner and

Grimm, 2006; Tait and Green, 2010; Kroemer *et al.*, 2007). According to current models, MPT is mediated by the opening of the PTPC, a poorly characterized multiprotein complex assembled at the interface of the IMM and OMM, exhibiting Ca^{2+} -activatable, voltage-dependent, and cyclosporin A-sensitive channel activity (Brenner and Grimm, 2006; Yu *et al.*, 2001). Throughout the past two decades, several proteins have been suspected to constitute key structural or regulatory subunits of the PTPC, including (1) various isoforms of the voltage-dependent anion channel (VDAC) and translocator protein (18 kDa) (TSPO, best known as peripheral benzodiazepine receptor), which are embedded in the OMM (Tajeddine *et al.*, 2008; Galluzzi and Kroemer, 2007; Azarashvili *et al.*, 2007; Pastorino *et al.*, 1994; Szabo *et al.*, 1993; Szabo and Zoratti, 1993; Mcenery *et al.*, 1992); (2) multiple variants of ANT and solute carrier family 25 member 3 (SLC25A3, best known as phosphate carrier), which are inserted into the IMM (Pauleau *et al.*, 2008; Alcalá *et al.*, 2008; Palmieri, 2004; Ruck *et al.*, 1998; Beutner *et al.*, 1996, 1998); (3) CYPD, a protein of the mitochondrial matrix (Martel *et al.*, 2012; Schinzel *et al.*, 2005; Baines *et al.*, 2005; Basso *et al.*, 2005); (4) creatine kinase, mitochondrial 1 (CKMT1), a protein of the IMS (Beutner *et al.*, 1996, 1998; Verrier *et al.*, 2004); as well as (5) hexokinase 1 (HK1), HK2, glycogen synthase kinase β (GSK3 β), and protein kinase C ϵ (PKC ϵ), all of which are cytosolic proteins (Beutner *et al.*, 1996, 1998; Verrier *et al.*, 2004; Chiara *et al.*, 2008; Baines *et al.*, 2003; Galluzzi *et al.*, 2008b). Robust genetic evidence argues against a key role for most of these proteins (Galluzzi and Kroemer, 2007; Baines *et al.*, 2007; Kokoszka *et al.*, 2004), with the notable exception of CYPD (Schinzel *et al.*, 2005; Baines *et al.*, 2005; Nakagawa *et al.*, 2005). However, it seems unlikely that CYPD might constitute the actual pore-forming unit of the PTPC, for at least two reasons. First, CYPD is not embedded into the IMM but localized to the mitochondrial matrix. Second, *Ppif*^{-/-} mitochondria exhibit a pronounced shift in the concentration of Ca^{2+} ions that is required to open the PTPC, yet remain capable of undergoing MPT (Schinzel *et al.*, 2005; Baines *et al.*, 2005; Nakagawa *et al.*, 2005; Basso *et al.*, 2005). Data accumulating in the last few years indicate that the F_1F_0 -ATPase, in particular the c subunit, may play a key structural role within the PTPC, perhaps even constituting the long-sought pore-forming component (Bonora *et al.*, 2013, 2015; Giorgio *et al.*, 2013; Bernardi, 2013). Formal evidence in support of this notion, however, is still lacking. Actually, the molecular composition of the PTPC appears to be very dynamic, which has led some investigators to speculate that most, if not all, mitochondrial proteins might become able to assemble a relatively unspecific channel under some circumstances (Brenner and Moulin, 2012; Brenner and Grimm, 2006), a hypothesis that is still awaiting experimental confirmation.

Also the precise molecular mechanisms underlying MPT remain elusive. Indeed, while several reports indicate that the PTPC would trigger MPT upon the assumption of a high-conductance state (Zoratti *et al.*, 2010; Zoratti and Szabo, 1994; Zorov *et al.*, 1992), others suggest that MPT ensues the closure of the PTPC, resulting in an osmotic imbalance that eventually compromises the structural integrity of mitochondria (Vander Heiden and Thompson, 1999; Vander Heiden *et al.*, 1999, 2001). A model reconciling these apparently discrepant

interpretations has not yet been put forward. Irrespective of these mechanistic incognita, the MPT as triggered by cytosolic Ca^{2+} waves and oxidative stress has been shown to constitute an etiological determinant in several pathophysiologically relevant instances of cell death (see above).

Intriguingly, several members of the Bcl-2 proteins as well as p53 have been shown to interact with, thereby regulating the activity of, several proteins that have been involved in the PTPC (Vaseva *et al.*, 2012; Shimizu *et al.*, 1999; Vander Heiden *et al.*, 1999). In particular, BCL-2 and BCL-X_L reportedly inhibit MPT by controlling the conductance of VDAC1 (Shimizu *et al.*, 1999; Vander Heiden *et al.*, 1999). Moreover, BAX, BAK1, and BID have been shown to stimulate MPT by interacting with ANT1 or VDAC1 (Karch *et al.*, 2013; Marzo *et al.*, 1998; Zamzami *et al.*, 2000; Narita *et al.*, 1998). Along similar lines, BAD appears to initiate MPT in a VDAC1-dependent, BCL-X_L-sensitive manner, possibly owing to its ability to displace VDAC1 from inhibitory interactions with BCL-X_L (Roy *et al.*, 2009). Finally, a pool of p53 localized to the mitochondrial matrix has recently been suggested to contribute to MPT-driven regulated necrosis by physically interacting with CYPD (Vaseva *et al.*, 2012). Conversely, putative PTPC constituents may mediate MOMP-regulatory functions. In particular, VDAC2 has been shown to mediate robust cytoprotective effects owing to its ability to sequester active BAK1 (Cheng *et al.*, 2003). Thus, MPT not only delineates the frontiers between a cell's life and death in several instances of apoptosis and regulated necrosis, but is also intimately intertwined with MOMP in the context of a multipronged, mutually regulatory interaction (Figure 3).

Concluding Remarks

Mitochondria not only are essential for the survival of eukaryotic cells but also control several cell death subroutines, including most instances of apoptosis, MPT-driven necrosis and parthanatos (Galluzzi *et al.*, 2014a; Kroemer *et al.*, 2007; Tait and Green, 2010; Vanden Berghe *et al.*, 2014; Vandenabeele *et al.*, 2010). In addition, several mitochondrial constituents operate as damage-associated molecular patterns, alerting the organism of a threatening condition and eliciting an innate immune response aimed at the reestablishment of systemic homeostasis (Galluzzi *et al.*, 2012a; Tait and Green, 2012). Whether the pronounced ability of mitochondria to elicit cellular and organismal adaptive responses reflects (at least to some extent) their foreign evolutionistic derivation remains to be determined. Irrespective of this conundrum, mitochondria nowadays stand out as key regulators of cellular and organismal danger signaling (Galluzzi *et al.*, 2012a; Tait and Green, 2012).

Glossary

Biologics A class of therapeutics composed of proteins or nucleic acids.

Death domain (DD) A protein module composed of a bundle of six α -helices. The DD is essential to generate a signal leading to apoptosis.

Inflammation A localized physical condition in which part of the body becomes reddened, swollen, hot, and often painful, especially as a reaction to injury or infection.

Ligand A molecule, such as a hormone, cytokine, or drug that binds to a specific receptor.

Phosphorylation A covalent attachment of a phosphoryl group to a serine, threonine, or tyrosine residue of a target protein.

Receptor A protein molecule in a cell or on the surface of a cell to which a ligand can bind, causing a change in the activity of the cell.

Signal transduction A set of reactions in a cell that occurs when a ligand attaches to a receptor leading to a cascade of biochemical reactions inside the cell that eventually reach the target molecule or reaction.

Tumor necrosis factor (TNF) A multifunctional proinflammatory cytokine that can bind to, and thus functions through its receptors TNFR1 (aka CD120a) and TNFR2 (aka CD120b). It is involved in the regulation of various biological processes including cell proliferation, differentiation, and cell death.

Ubiquitination A covalent attachment of the ubiquitin, a 76-amino-acid-comprising protein, via its C-terminus to an amino group on a target protein.

Introduction

Tumor necrosis factor (TNF) is the namesake member of a large superfamily of structurally related cytokines that are involved in many physiologic functions (Wiens and Glenney, 2011; Bodmer *et al.*, 2002; Locksley *et al.*, 2001). Discovered and rediscovered through its antitumor, septic shock, cytotoxic, and cachectic activities (Ruddle, 2014; Cerami and Beutler, 1988), TNF has emerged as a key host defense mechanism against infections.

TNF mediates its activity by engaging two specific cell surface receptors, themselves members of a superfamily of structurally related proteins. TNF receptors (TNFRs) activate signaling pathways leading to cellular differentiation, growth, and death (Walczak, 2011; Sun, 2011). The signaling pathways activated by TNFRs depend on many factors such as the cellular expression patterns of the receptors and signaling proteins (Schrofelbauer and Hoffmann, 2011). TNF receptor-1 (TNFR1, aka p55/60) and TNF receptor-2 (TNFR2, aka p75/80) differ structurally in their cytoplasmic regions and engage different sets of signaling proteins that directly contribute to differences in cellular responses.

TNF is one component of a larger network of cytokine signaling systems that controls many aspects of the innate and adaptive arms of the immune system (Ware, 2005; Commerman *et al.*, 2014). This network is defined by the shared usage of ligands and receptors, however, each ligand-receptor system activates signaling that initiates unique cellular and physiologic responses. For example, TNFR1 and TNFR2 engage another ligand, Lymphotoxin- α (LT α), which forms yet another ligand with Lymphotoxin- β that binds specifically to LT β receptor. The LT β receptor engages yet another ligand, termed LIGHT (lymphotoxin-like, exhibits inducible

expression, and competes with herpes simplex virus glycoprotein D for HVEM, a receptor expressed by T lymphocytes) (TNFSF14), which itself engages other receptors, Herpesvirus entry mediator (HVEM, TNFRSF14) and decoy receptor 3 (DcR3) (Ware and Sedy, 2011). A pivotal point in signaling is the ability of HVEM to engage receptors in the immunoglobulin superfamily, B- and T-lymphocyte attenuator, which limits immune responses (Murphy and Murphy, 2010). Together, this network forms an integrated system that allows communication among immune cells and tissue cells in their microenvironment and at distant sites.

The clinical relevance of research in signaling pathways emerged with the realization that antibody-based inhibitors of TNF alleviate inflammation and disease symptoms in patients with certain autoimmune diseases (Feldmann *et al.*, 1992). A significant fraction of patients with moderate to severe rheumatoid arthritis, psoriasis, or inflammatory bowel disease respond to antibodies or decoy receptors that competitively block TNF from engaging its specific receptors. The impact of TNF inhibitors is a major clinical advance that has spurred research into other TNF-related cytokines and their signaling pathways in pursuit of ways to alter human diseases (Croft *et al.*, 2013).

In this article we summarize the current state of the art for signaling pathways initiated by TNF and their relationship to cellular responses and disease.

The TNF and TNFR Superfamilies

The TNF superfamily (TNFSF) is composed of 19 structurally related proteins (ligands). These ligands bind to one or more molecules from the TNFR superfamily (TNFRSF), which

Table 1 Members of TNFSF

Symbol	Approved name	Synonyms	Chromosome
CD40LG	CD40 ligand	CD40L, TRAP, gp39, hCD40L, CD154	Xq26
CD70	CD70 molecule	CD27L	19p13
EDA	Ectodysplasin A	EDA1, XLHED, HED, XHED, ED1-A1, ED1-A2, EDA-A1, EDA-A2	Xq12-q13.1
FASLG	Fas ligand (TNF superfamily, member 6)	FasL, CD178	1q23
LTA	Lymphotoxin alpha	TNFSF1, LT	6p21.3
LTB	Lymphotoxin beta	p33, TNFSF3	6p21.3
TNF	Tumor necrosis factor (TNF)	TNFSF2, DIF, TNF-alpha	6p21.3
TNFSF4	TNF superfamily, member 4	OX-40L, gp34, CD252	1q25
TNFSF8	TNF superfamily, member 8	CD153	9q33
TNFSF9	TNF superfamily, member 9	4-1BB-L	19p13.3
TNFSF10	TNF superfamily, member 10	TRAIL, Apo-2L, TL2, CD253	3q26
TNFSF11	TNF superfamily, member 11	TRANCE, RANKL, OPGL, ODF, CD254	13q14
TNFSF12	TNF superfamily, member 12	TWEAK, DR3LG, APO3L	17p13.1
TNFSF13	TNF superfamily, member 13	APRIL, CD256	17p13.1
TNFSF13B	TNF superfamily, member 13b	BAFF, THANK, BLYS, TALL-1, TALL1, CD257	13q32-q34
TNFSF14	TNF superfamily, member 14	LIGHT, CD258	19p13.3
TNFSF15	TNF superfamily, member 15	TL1, VEGI, TL1A, VEGI192A, MGC129934, MGC129935	9q32
TNFSF18	TNF superfamily, member 18	AITRL, TL6, hGITRL	1q23

consists of 29 structurally similar receptors. The members of TNFSF and TNFRSF are listed in [Tables 1](#) and [2](#), respectively.

The members of TNFSF are generally type II transmembrane proteins (intracellular N-terminus) having a trimeric TNF homology domain (THD), comprising of three jelly-roll protomers to form a biologically active trimer. These domains are located at the C-terminal region of the protein. All members of the TNF family form homotrimers. The exception is LT β , which functions by forming heterotrimer with LT α . All except LT α (which is entirely secreted) are transmembrane proteins that either act by cell-to-cell contact and can be cleaved by proteolysis (shedding) from the cell surface into a soluble form.

Members of the TNFRSF are type I transmembrane proteins (N-terminus exterior to the cell). In contrast to the compact structure of the ligands, the receptors have an elongated extracellular ligand-binding domain defined by a cysteine-rich amino acid motif that recurs three to six times. This motif is known as CRD (cysteine-rich domain) and typically contains six cysteines forming three disulfides. The receptors also have relatively large cytosolic domains that engage different signaling proteins.

The receptor-binding site in TNF is created by interactions between adjacent subunits, thus a trimer creates three receptor-binding sites ([Banner et al., 1993](#)). High-affinity ligand binding induces clustering of the cognate cell surface receptors, which creates the cytosolic domains into a binding platform allowing recruitment of signaling molecules that initiate signal transduction. Bivalent antibodies to TNFR or overexpression can trigger receptor activation mimicking the natural ligand. Cells maintain low expression of TNFR, often only a few thousand molecules per cell, to limit spontaneous signaling.

Structural Features of TNF, TNFR1, and TNFR2

TNF is a 233 amino acid (aa) residue (26 kDa) protein, with a short 29 aa residue cytoplasmic domain, a 28 aa residue

transmembrane segment, and a 176 aa residue extracellular region containing the THD where the receptor-binding sites are located ([Wajant et al., 2003](#)). The 17 kDa TNF protomers are composed of two stacked β -pleated sheets with five anti-parallel β -strands, forming a 'jelly-roll' β -structure. The inner β -sheet is involved in contacts between adjacent subunits, which promotes assembly into a trimer. The trimer is formed such that one edge of each subunit is packed against the inner sheet of its neighbor. The outer β -sheet is surface exposed. The surface exposed loops are involved in receptor binding. The functional unit of the ligand is the assembly of THD into trimers. Membrane TNF, as a transmembrane protein expressed on the surface of cells, is cleaved by a metalloprotease, TNF-converting enzyme (TACE) ([Black et al., 1997](#)) which liberates a trimeric soluble cytokine ([Figure 1](#)). The soluble form of TNF circulates throughout the body to confer TNF with its potent endocrine function – an ability to act at distant sites, far from the site of synthesis.

TNF biosynthesis is initiated by innate immune sensor receptors, such as toll-like receptors (TLRs) as well as antigen receptors of T and B lymphocytes. TLRs are a class of proteins that play a critical role in the early innate immune response to pathogens. TLRs recognize structural motifs found associated with microorganisms, known as pathogen-associated molecular pattern molecules, such as lipopolysaccharides, bacterial DNA, and viral double-stranded RNA, or molecules associated with cellular damage, such as heat shock proteins as well as protein fragments released from necrotic or dying cells. Stimulation of TLRs by the danger molecules initiates signaling cascade that activates the transcription factor NF- κ B (nuclear factor- κ B) and other transcription factors, which in turn leads to production of proinflammatory cytokines including TNF and type 1 interferons ([Beutler, 2009](#)). The production of TNF mRNA is regulated by NF- κ B, c-Jun, activator protein 1 (AP1), and nuclear factor associated with activated T cells (NFAT) transcription factors, which is consistent with the fact that the promoter region of the TNF gene has binding sites for these

Table 2 Members of TNFRSF

<i>Symbol</i>	<i>Approved name</i>	<i>Synonyms</i>	<i>Chromosome</i>
CD27	CD27 molecule	S152, Tp55	12p13
CD40	CD40 molecule, TNF receptor superfamily member 5	p50, Bp50	20q12-q13.2
EDA2R	Ectodysplasin A2 receptor	XEDAR, EDA-A2R, EDAA2R, TNFRSF27	Xq11.1
EDAR	Ectodysplasin A receptor	ED5, EDA3, Edar, ED1R, EDA1R	2q13
FAS	Fas cell surface death receptor	CD95, APO-1	10q24.1
LTBR	Lymphotoxin beta receptor (TNFR superfamily, member 3)	TNFCR, TNFR-RP, TNFR2-RP, TNF-R-III, TNFRSF3	12p13
NGFR	Nerve growth factor receptor	TNFRSF16, CD271, p75NTR	17q21-q22
RELT	RELT tumor necrosis factor receptor	FLJ14993	11q13.2
TNFRSF1A	TNFRSF, member 1A	TNF-R, TNFAR, TNFR60, TNF-R-I, CD120a, TNF-R55	12p13.2
TNFRSF1B	TNFRSF, member 1B	TNFBFR, TNFR80, TNF-R75, TNF-R-II, p75, CD120b	1p36.22
TNFRSF4	TNFRSF, member 4	ACT35, OX40, CD134	1p36
TNFRSF6B	TNFRSF, member 6b, decoy	DcR3, DCR3, TR6, M68	20q13.33
TNFRSF8	TNFRSF, member 8	KI-1	1p36
TNFRSF9	TNFRSF, member 9	CD137, 4-1BB	1p36
TNFRSF10A	TNFRSF, member 10a	DR4, Apo2, TRAILR-1, CD261	8p21
TNFRSF10B	TNFRSF, member 10b	DR5, KILLER, TRICK2A, TRAIL-R2, TRICKB, CD262	8p22-p21
TNFRSF10C	TNFRSF, member 10c, decoy without an intracellular domain	DcR1, TRAILR3, LIT, TRID, CD263	8p22-p21
TNFRSF10D	TNFRSF, member 10d, decoy with truncated death domain	DcR2, TRUNDD, TRAILR4, CD264	8p21
TNFRSF11A	TNFRSF, member 11a, NF- κ B activator	RANK, CD265, FEO	18q22.1
TNFRSF11B	TNFRSF, member 11b	OCIF, TR1	8q24
TNFRSF12A	TNFRSF, member 12A	FN14, TweakR, CD266	16p13.3
TNFRSF13B	TNFRSF, member 13B	TACI, CD267, IGAD2	17p11.2
TNFRSF13C	TNFRSF, member 13C	BAFFR, CD268	22q13.1-q13.3
TNFRSF14	TNFRSF, member 14	HVEM, ATAR, TR2, LIGHTR, HVEA, CD270	1p36.32
TNFRSF17	TNFRSF, member 17	BCM, CD269, TNFRSF13A	16p13.1
TNFRSF18	TNFRSF, member 18	AITR, GITR, CD357	1p36.3
TNFRSF19	TNFRSF, member 19	TAJ-alpha, TROY, TAJ, TRADE	13q12.11-q12.3
TNFRSF21	TNFRSF, member 21	DR6, CD358	6p21.1
TNFRSF25	TNFRSF, member 25	DR3, TRAMP, WSL-1, LARD, WSL-LR, DDR3, TR3, APO-3	1p36.2

transcription factors (Tuohy *et al.*, 1998). Posttranscriptional mRNA regulation also occurs by the actions of miRNAs and RNA-binding proteins, such as tristetraprolin, mRNA decay factors, and specific 3'-untranslated region AU-rich elements (Stamou and Kontoyiannis, 2010; Gherzi *et al.*, 2004).

Both soluble and membrane TNF bind to two transmembrane receptor molecules: TNFR1 and TNFR2 (Tartaglia *et al.*, 1991). TNFR1 is a 455 aa residue (55 kDa) transmembrane glycoprotein. The molecule has a 190 aa residue extracellular region, a 25 aa residue transmembrane segment, and a 220 aa residue cytoplasmic domain. The extracellular region has four cysteine-rich motifs. The cytoplasmic domain has an 80 aa residue folding into α -helical bundle known as a 'death domain' that can trigger apoptotic pathway. TNFR2 is a 461 aa residue (75 kDa) transmembrane glycoprotein. This receptor consists of a 240 aa residue extracellular region, a 27 aa residue transmembrane segment and a 173 aa residue cytoplasmic domain, which contains structurally defined sequence known as the TRAF (TNFR-associated factor)-binding motif. The

patterns of receptor expression determine the responsiveness of a cell. Most cells express low but constitutive levels of TNFR1, while only some cells (endothelial cells, dendritic cells and macrophages, and activated lymphocytes) express TNFR2 (see Immunological Genome Project and BioGPS in Relevant Websites section for more details).

TNF-Induced TNFR Signaling

Signaling begins upon binding TNF to either TNFR1 or TNFR2. The affinity of TNF binding is high with a K_d in the piconanomolar range. The propagation of signals from receptor to enzymatically active proteins is mediated by two distinct types of signaling motifs in the cytosolic domain of the TNFR: Death Domains (DD) and TRAF-binding motifs. The death domain in TNFR1 is composed of six α -helices arranged antiparallel to one another. The DD serves as a protein-interaction site and participates in homotypic interactions with the DD containing

Figure 1 TNF Receptor and ligand complex. Membrane-bound TNF (mTNF) and soluble TNF (sTNF) derived by the action of TNF α -converting enzyme (TACE) bind to two members of the TNF-receptor superfamily, TNFR1 and TNFR2. Membrane TNF activates both TNFRs. Soluble TNF predominantly stimulates TNFR1 and has limited signaling capacities on TNFR2. Activation of TNFR1 and TNFR2 followed by recruitment of adaptors, TRADD and TRAF2, respectively initiates signaling events ranging from NF- κ B and MAPK signaling pathways to apoptosis.

proteins such as TNF receptor type 1-associated death domain protein (TRADD) and Fas-associated death domain containing protein (FADD). In contrast, TNFR2 initiates signaling through a TRAF-binding motif (~ 20 residues in length) that binds selectively to members of the TRAF family, TRAF2 and TRAF3.

TNFRs initiate intracellular signaling pathways that culminate in active transcription factors such as NF- κ B or AP1 (Mak and Yeh, 2002) that in turn control the expression of hundreds of genes that alter cellular differentiation. TNFR initiate the formation of active transcription factors by activating key enzymes including protein kinases, proteases, ubiquitin E3 ligases, and deubiquitinases. TNFR activation initiates several posttranslational modifications including serine phosphorylation and ubiquitination of the signaling components that fine tune the activation of transcription factors. These covalent modifications alter the properties of the target protein, thereby allowing a rapid alteration in the activity and/or the expression of signaling intermediates.

TNFR-Induced NF- κ B Activation

TNFR signaling results in the activation of several transcription factors, of which NF- κ B is critically important for induction of proinflammatory activity required for host defense. NF- κ B comprises a family of structurally related transcription factors that are involved in the control of a large number of cellular

processes, such as immune and inflammatory responses, developmental processes, cellular growth, and apoptosis. Upon ligand-dependent receptor oligomerization, the second step in the TNFR1 signaling is the recruitment of the adapter molecules, TRADD and receptor-interacting protein kinase 1 (RIPK1) to the receptor cytosolic domain, and then TRAF2 to TRADD, to form an enzymatic complex referred to as signaling complex I (Micheau and Tschopp, 2003). TRAF proteins contain an N-terminal RING domain, followed by several zinc fingers and a C-terminal domain (CTD) containing a coiled-coil (CC) and the TRAF-C region (Huxford and Ghosh, 2009). The C-terminal part of TRAFs facilitates trimerization and is involved in direct interactions with the TNFR2 and adaptor proteins, such as TRADD. The N-terminal region of TRAFs mediates dimerization (Bianchi and Meier, 2009). Mitogen-activated protein kinase kinase kinases (MAP3Ks) are then recruited and activated by the complex I. Activated MAP3Ks phosphorylate inhibitors of κ B (I κ B) to initiate the multi-protein enzyme complex called I κ B kinase (IKK) complex. The core of the IKK complex consists of two catalytic subunits, IKK α and IKK β , and a regulatory/scaffold subunit, NF- κ B essential modulator (NEMO or IKK γ). Subsequently, cIAP1/cIAP2 are recruited to the complex I through the coiled-coil region of the TRAF2 (Bianchi and Meier, 2009). Within this complex, RIPK1, TRAFs, and NEMO undergo several forms of ubiquitination, primarily conjugation of K63 or head-to tail (linear) polyubiquitin chains. K63 ubiquitination of RIPK1

and NEMO is catalyzed by the E3 ligase activity of cIAP1/cIAP2 or TRAF2 together with Uev1A and Ubc13 (Bertrand *et al.*, 2008). RIPK1 and NEMO undergo linear poly-ubiquitination by linear ubiquitin chain assembly complex (LUBAC), which consists of HOIL-1, HOIP, and SHARPIN (Tokunaga *et al.*, 2009). Ubiquitination of RIPK1 serves as a platform for the assembly of downstream IKK activating kinases. First, the transforming growth factor (TGF)- β activating kinase 1 (TAK1) is recruited by specific binding of its adaptors, TAK1-binding protein 2 (TAB2) and TAB3, through the ubiquitin chains (Ea *et al.*, 2006). TAK1 itself is K63 ubiquitinated, which triggers its autophosphorylation and activation (Scholz *et al.*, 2010).

In mammalian cells, the NF- κ B family consists of five members: RelA, RelB, c-Rel, p50/NF- κ B B1, and p52/NF- κ B B2 (proteolytic processing of p105 and p100 yields the active forms p50 and p52, respectively) (Ghosh *et al.*, 1998; Karin and Ben-Neriah, 2000). The translocation of NF- κ B leads to their activation (Schrofelbauer and Hoffmann, 2011). Homo- and hetero-dimers of NF- κ B family members are held inactive in the cytosol by I κ B, such as I κ B α , which mask nuclear localization motifs on the NF- κ B dimers. The binding of NEMO to ubiquitin chains brings IKK in close proximity to TAK1, which in turn leads to serine phosphorylation of residues in the activation loop of IKK (Tokunaga *et al.*, 2009). Activation of the NEMO-IKK complex results in phosphorylation and ubiquitin-dependent degradation of the inhibitor of I κ B proteins within the cell cytoplasm, which unmasks a nuclear translocation sequence on subunits of NF- κ B, enabling heterodimeric NF- κ B to enter into the nucleus where it binds to the enhancer of its target genes (Baldwin, 1996). Events leading to TNF-induced NF- κ B activation are diagramed in Figure 2.

TNFR2 directly interacts with TRAF2 through TRAF-binding motif and it lacks a DD indicating it does not directly activate caspases for apoptotic death. TNFR2 signaling follows the noncanonical NF- κ B pathway that regulates the activation of RelB form of NF- κ B through the NF- κ B-inducing kinase (NIK) and IKK α kinase. In unstimulated cells, NIK levels are maintained at vanishing low levels by ubiquitination and proteasome degradation through an E3 ligase complex comprised of TRAF3, TRAF2, and cIAP1/cIAP2 (Sun, 2011). Receptor ligation releases the active form of NIK by competitively displacing TRAF3 preventing further ubiquitination allowing NIK to accumulate (Sanjo *et al.*, 2010). NIK phosphorylates IKK α , which induces the proteasome-dependent processing of p100 to p52, degrading the inhibitory domain of p100 and allowing the RelB-p52 complex to activate gene transcription (Figure 2).

TNFR-Induced Cell Death

TNF-induced cell death signaling is carried out by TNFR1 (Tartaglia *et al.*, 1993). Ligation of TNFR1 promotes recruitment of intracellular 'death-inducing signaling complex' (DISC) proteins, including TRADD and FADD (Hsu *et al.*, 1996). These proteins create a scaffold permitting the recruitment and dimerization of caspase-8 (an initiator caspase), forming an active enzyme complex referred to as complex II (Micheau and Tschopp, 2003). Activated caspase-8 acts directly to cleave procaspase-3 and -7, which are known as the

executioner caspases as they directly cleave critical cellular substrates leading to apoptotic death (Ho and Hawkins, 2005; Figure 2). The activation of caspase-3, is essential for TNF-induced cell death, as it targets a latent DNase, the caspase-activated DNase (CAD), that degrades genomic DNA, a feature of apoptotic cell death (Enari *et al.*, 1998). Caspase-8 also cleaves BID, a mediator of mitochondria damage-associated cell death, an event that greatly amplifies the apoptotic process (Green *et al.*, 2011).

TNFR signaling induces a variety of genes that can inhibit cell death pathways. For example, the protease activity of caspase-8 is tightly regulated by a negative inhibitor protein FLICE (caspase-8) inhibitory protein (FLIP). cFLIP lacks a death domain but contains a death-effector domain (DED). DED allows its interactions with procaspase-8 as well as other DED containing proteins (Muzio *et al.*, 1997), which prevents constitutive procaspase-8 recruitment and activation to the TNFR1 DISC.

TNF activation-induced c-Jun-terminal kinase (JNK) pathway mediates phosphorylation and activation of the E3 ubiquitin ligase Itch, which specifically ubiquitinates cFLIP. Ubiquitination of cFLIP induces its proteasomal degradation, hence coupling JNK activation to TNF-induced cell death (Chang *et al.*, 2006). The inhibitor of apoptosis proteins (IAPs) are also important regulators of TNFR-induced cell death. IAPs are E3 ubiquitin ligases that inhibit caspases by acting with TRAF2 (Vince *et al.*, 2009). Both FLIP and IAPs are NF- κ B regulated genes. Thus, activation of TNFR1 induces a caspase-dependent apoptotic cell death that is tightly regulated by cFLIP and IAPs. Although TNF is a powerful inducer of apoptotic cell death, it induces cell death in transformed cells (Munker and Koeffler, 1987), virus infected cells (Sedger *et al.*, 1999), stressed cells, but not in most normal cells.

TNF has potent antiviral activity, which is mediated through TNFR 1 and TNFR 2. Many viruses have evolved mechanisms that specifically inhibit different steps of TNFR-induced apoptosis and NF- κ B signaling pathways (Hiscott *et al.*, 2006). Indeed most poxviruses express a pan-caspase inhibitor such as CrmA (Tewari and Dixit, 1995), and certain herpes viruses encode a FLIP ortholog that inhibits caspase-8 (Thome *et al.*, 1997).

Regulation of TNF Signaling by Ubiquitin Ligases and Deubiquitinases

The signaling complexes formed due to ligation of TNF to its receptors may be inactivated by the deubiquinating enzyme A20 (or TNFAIP3) which is thought to regulate RIP1 ubiquitination. A20 contains both an ovarian tumor (OUT) deubiquitinase domain and a coiled-coil zinc finger E3 ligase motif. A20 attenuates NF- κ B signaling in a two-step process. The A20 DUB domain first removes K63-linked ubiquitin chains from RIP1, and the A20 E3 ligase domain then promotes RIP1 K48 ubiquitination. As K63-ubiquitinated RIP1 is required for NF- κ B activation, A20-mediated RIP1 K63 de-ubiquitination and subsequent K48 ubiquitination-dependent proteasomal degradation cooperate to downregulate NF- κ B signaling (Wertz *et al.*, 2004). Upon TNF stimulation, the cellular zinc finger anti-NF- κ B protein Cezanne is also recruited to TNFR1 and promotes RIP1 de-ubiquitination, thereby attenuating NF- κ B

Figure 2 TNFR signaling pathways. Binding of trimeric TNF to TNF receptor-1 (TNFR1) leads to receptor trimerization and formation of TNF receptor signaling complex, also known as complex I. Then, the signaling molecules TNFR1-associated death domain (TRADD) and receptor-interacting protein kinase 1 (RIPK1) are recruited via their DDs to the complex I. Through TRADD, TNFR-associated factor 2 (TRAF2) is then recruited, which in turn recruits cIAP1 and cIAP2. The cIAPs then cause K63 (blue chains) and possibly also K48-linked ubiquitin (green chains) to different components of the complex. The LUBAC is then recruited to the complex I in a TRADD-, TRAF2-, and cIAP1/cIAP2-dependent manner. LUBAC activity in the complex I results in linear ubiquitination of RIPK1 and NF-κB essential modulator (NEMO) (red chains). The action of different E3 ubiquitin ligases facilitates the recruitment and positioning of the NEMO/IKK and TAK-binding protein/transforming growth factor β -activated kinase (TAB/TAK) complexes which enables the NF-κB and MAPK pathways to be activated. After a delay, and probably as a consequence of de-ubiquitination events at the membrane-bound TNFR signaling complex, carried out by de-ubiquitylating enzymes, A20 and CYLD, the composition of the complex changes, and a second complex, called complex II forms in the cytosol. Complex II recruits FADD and procaspase-8. This leads to activation of caspase-8 leading to its processing. Activated caspase-8 cleaves downstream effector caspases (caspase-3 and caspase-7). Proteolytic processing of caspase-3 and caspase-7 is responsible for the induction of cell death. Trimeric TNF can also bind to TNFR2 leading to recruitment of TRAF2, TRAF3, and cIAPs. This leads to degradation of TRAF2 and TRAF3 resulting in NIK accumulation. NIK in turn stimulates the IKK α , which then leads to phosphorylation of p100. This event leads to proteasome-dependent partial processing of p100 to p52, which in turn binds to RelB to form an active NF-κB dimer, hence activating an alternate NF-κB pathway. Blue, red, and green circles represent K63, linear, and K48 ubiquitin chains, respectively.

signaling (Enesa *et al.*, 2008). The tumor suppressor CYLD (cylindromatosis (turban tumor syndrome)) is also proposed to de-ubiquitinate K63-linked chains from RIPK1, NEMO, and TRAF proteins to attenuate downstream signaling cascades (Kovalenko *et al.*, 2003).

TNF-Induced Activation of MAPK Pathways

In addition to the activation of IKK, TNFR1 also leads to the potent activation of other kinases – JNK, p38, and ERK1/ERK2.

Activation of JNK depends on TRAF2 and on the formation of K63 ubiquitin chains (Fukushima *et al.*, 2007). Activation of p38 also depends on TRAF2 and RIPK1 (Lee *et al.*, 2003). Several MAP3Ks have been implicated in the activation, including MEKK1 (Takaesu *et al.*, 2000), TPL-2 (Das *et al.*, 2005), and ASK1 (Takaesu *et al.*, 2000). MAP3Ks then phosphorylate and activate MAP2Ks. While MKK3 and MKK6 specifically phosphorylate and activate p38, MKK7 activates JNK. MKK4 is less specific and can activate both p38 and JNK (Wang *et al.*, 2007). The main activator of the TNF-induced ERK1/ERK2 signal transduction pathway is TPL-2 (Eliopoulos *et al.*, 2003).

Table 3 Human genetic diseases associated with mutations in the components of TNF signaling pathway

Protein	Disease	Mutation
A20	Rheumatoid arthritis, systemic lupus erythematosus (SLE)	Phe127Cys
Caspase-8	Breast cancer, immune deficiency	Arg189Trp, Asp243His, Arg248Trp
CYLD	Multiple familial trichoepithelioma, familial cylindromatosis	Glu747Gly, Gln710X (missense mutation), Asp941Val, Arg758Ter
HOIL-1	Susceptibility to infection by pyogenic bacteria and auto-inflammation	Q185X (missense mutation)
IKK1	Cocoon syndrome	Gln422Ter
I κ B α	Ectodermal dysplasia	Ser32Ile, Glu14Ter, Ser32Ile, Trp11Ter
NEMO	Incontinentia pigmenti	Glu57Lys, Arg123Trp, Ala323Pro, Met339Val
	Ectodermal dysplasia, hypohidrotic, with immune deficiency	Leu153Arg, Leu85Arg, Leu227Pro, Ala220Gly, Asp311Asn, Gln335Ter, Glu323Ter, Cys349Arg, Cys349Phe
	Recurrent isolated invasive pneumococcal disease	Ter352Trp, Arg173Gly, Arg175Pro
	Susceptibility to Mycobacterial disease	Arg251Gln, Glu247Ala
	X-linked familial atypical micobacteriosis	Arg319Gln, Glu315Ala
	Lymphedema dysplasia, ectodermal dysplasia	Asp338Val, Asp406Val, Cys417Arg, Cys417Phe, Cys417Tyr, Met407Val
NIK	B-cell lymphopenia, decreased frequencies of class-switched memory B cells	Pro565Arg
TAB2	Congenital heart defects	Gln230Lys, Pro208Ser, Gln230Lys, Pro208Ser
TNFR1	Familial periodic fever	Mutation in first cysteine-rich domain
TRAF3	Herpes simplex encephalitis 3	Arg118Trp
XIAP	Lymphoproliferative syndrome	Glu118Ter, Cys203Tyr

Physiologic Functions of TNF and Disease Relevance

Even though most of our understanding about the physiological functions of TNF came from gene targeting approaches in mice, pre-knockout studies identified two important opposite functions of TNF. In mice, systemic bacterial infection leads to the overproduction of TNF causing a profound shock syndrome (Tracey *et al.*, 1987). In contrast to this deleterious effect, there was beneficial effect of TNF due to the stimulation of protective granuloma formation during mycobacterial infections (Flynn *et al.*, 1995). In the first knockout mice for TNFR1, two main functions of TNFR signaling were reported, its protective role in intracellular bacterial infections (*Listeria*) and its detrimental role in LPS-mediated liver toxicity (Pfeffer *et al.*, 1993; Rothe *et al.*, 1993). TNF is disproportionally produced in humans and animal models with inflammatory and autoimmune disorders, rheumatoid arthritis, psoriasis, and inflammatory bowel disease. Various human diseases are associated with genetic deficiencies or mutations in members of TNF superfamilies as well as individual components of the TNF signaling pathway (summarized in Table 3). Selective targeting of these components to develop disease-modifying therapeutics is an active area of research.

TNF Inhibitors

TNF inhibitors are used in treating several autoimmune and inflammatory diseases. TNF inhibitors are specific antibodies or soluble receptors and are classified as biologics, i.e., protein-based drugs. Both antibody- and receptor-based drugs hinder the binding of TNF ligand to receptor, hence functioning as

competitive antagonists. Currently there are five approved anti-TNF antibody-based drugs (Figure 3). Etanercept is a fusion protein of the extracellular domain of TNFR 2 with the Fc (fragment, crystallizable) region of human IgG1 forming a bivalent molecule. This bivalent molecule has higher avidity for TNF than naturally occurring soluble receptors. Infliximab is a partially humanized mouse monoclonal antibody to human TNF. Adalimumab and golimumab are two fully human monoclonal antibodies. Certolizumab is a Fab' fragment of a humanized TNF inhibitor monoclonal antibody that is chemically modified with polyethyleneglycol (PEGylation) to prolong circulation half-life in patients.

Impact of TNF Blockade in Inflammatory Diseases

TNF is centrally involved in several inflammatory conditions (Phillips *et al.*, 2004). TNF inhibitors are approved for use in the treatment of rheumatoid arthritis (RA), ankylosing spondylitis, juvenile RA, Crohn's disease, psoriatic arthritis, and ulcerative colitis. RA is a chronic autoimmune disease with inflammation in the joints affecting mobility. Treatment of murine arthritis with antibodies against TNF or with soluble TNFR ameliorates the disease (Williams *et al.*, 1992). In humans, clinical studies demonstrated the efficacy of TNF-neutralizing antibody in reducing the progression and symptoms of RA (Elliott *et al.*, 1994). Treatment of RA is usually initiated with disease-modifying antirheumatic drugs such as methotrexate or corticosteroids to improve symptoms and reduce joint damage and TNF inhibitors given to patients with moderate to severe RA. Approximately 30% of patients with RA show a positive response to TNF inhibition, however, other patients show only a

Figure 3 TNF inhibitors. The diagram depicts the biologics (antibody-based inhibitors) used as TNF inhibitors that are approved for use in patients with autoimmune diseases. Adalimumab is a bivalent fully human monoclonal antibody, whereas certolizumab is a monovalent antibody fragment with enhanced half-life due to chemical addition of polyethylene glycol moieties. In contrast, etanercept is a bivalent fusion protein containing TNFR2 and the Fc region of human IgG1. Etanercept blocks both TNF and LT α from engaging their receptors (see text for details).

partial or no response. The inflammatory bowel diseases, ulcerative colitis (limited to colon and bowel), and Crohn's disease (entire intestine) are chronic inflammatory conditions where TNF is disproportionately expressed when the disease is active. Adalimumab, a fully human anti-TNF antibody is efficacious in controlled trials in patients with moderate to severe Crohn's disease (Hanauer *et al.*, 2006). Interestingly, etanercept is not effective in treating IBD, which may be due to the inhibition of LT α limiting IgA production (Kruglov *et al.*, 2013).

Skin lesions of psoriatic patients contain elevated levels of TNF, and following treatment with TNF inhibitors, serum and skin levels of TNF decrease with remarkable clinical response (Bonifati and Ameglio, 1999; Schon and Boehncke, 2005). In clinical trials, etanercept and infliximab significantly inhibited disease activity in patients suffering with psoriatic arthritis.

Even though TNF inhibitors are generally safe because of their specificity, side effects do occur with the use of TNF inhibitors. Such side effects include Lupus-like syndrome, aplastic anemia, hepatotoxicity, interstitial lung disease, optic neuritis, and exacerbations of quiescent multiple sclerosis. TNF inhibition is associated with diminished host defense. A systematic review of randomized clinical trials using infliximab

and adalimumab found a dose-related increase of some malignancies in RA patients (Bongartz *et al.*, 2006).

Caspases

Introduction

Caspases are a family of aspartate-specific, cysteine proteases. Mammalian interleukin-1 β -converting enzyme (ICE, later remained caspase-1) was the first member of the caspase family (Cerretti *et al.*, 1992; Thornberry *et al.*, 1992). As the name suggests, ICE/caspase-1 is required for the enzymatic processing and secretion of the pro-inflammatory cytokine IL-1 β . The product of the *Caenorhabditis elegans* cell death gene *ced-3* was shown to have a high degree of homology with ICE (Miura *et al.*, 1993; Yuan *et al.*, 1993). Given the essential role of *ced-3* in programmed cell death (PCD) in *C. elegans*, a functional link between caspase-1 and apoptosis was proposed (Miura *et al.*, 1993; Yuan *et al.*, 1993). Shortly after caspase-1, the neural precursor cell expressed developmentally downregulated gene 2 (*Nedd2*) sharing homology with *ced-3* was identified (Kumar *et al.*, 1992). Like *ced-3*, *Nedd2* (renamed caspase-2) encodes a cysteine-protease which, when overexpressed in mammalian cells, induced cell death by apoptosis (Kumar *et al.*, 1994). Given the main function of caspase-1 in cytokine maturation, caspase-2 was initially thought to functionally emulate *ced-3* in mammalian cell death (Kumar *et al.*, 1994; Miura *et al.*, 1993).

Since the initial discovery, 18 mammalian caspases have been identified with 12 encoded in the human genome (Eckhart *et al.*, 2008). Over the last two decades the structure, function, and enzymatic properties of the caspase family has been extensively characterized in mammals and other model organisms including *Drosophila melanogaster*. Much of the knowledge of the role of caspases in developmental PCD has come from *C. elegans*, as well as *D. melanogaster* (Kumar, 2007).

Structure, Classification, and Non-Apoptotic Biological Roles

Based on their structural and functional properties, caspases have been classified into three groups. Caspase-1, -4, and -5 are known as the inflammatory caspases and are involved in cytokine processing and coordination of inflammatory response (McIlwain *et al.*, 2013). Caspase-11 (the mouse orthologue of human caspase-4) and murine caspase-12 are also members of the inflammatory caspase family (McIlwain *et al.*, 2013). However, the evolutionary function of caspase-12 is not conserved as the human orthologue is a pseudo-caspase lacking a catalytic domain (Lamkanfi *et al.*, 2004). The second group of caspases are known as the apoptotic caspases and function as the initiators (caspase-2, -8, -9, and -10) or effectors (caspase-3, -6, and -7) of apoptosis (Kumar, 2007; McIlwain *et al.*, 2013). Most caspases are ubiquitously expressed in a wide range of tissues with the exception of some, such as caspase-14 whose expression is confined to keratinocytes where it is believed to function in differentiation (McIlwain *et al.*, 2013). Additional caspase family members,

caspase-13 (the bovine homolog of human caspase-4), -15, -16, -17, and -18 have also been identified in vertebrates, including various mammalian lineages (Eckhart *et al.*, 2008). Of these, only caspase-16 (which is most similar to caspase-14 in terms of sequence homology) is conserved in humans (Eckhart *et al.*, 2008). The biological functions of all mouse caspases (except caspase-16) have been interrogated by gene knockout models (Table 1). This has revealed an essential role for many caspases in development as well as apoptotic and non-apoptotic processes. Some caspases have been shown to be able to compensate for each other's functions; therefore double knockout strains have also been generated for some caspases to determine functional redundancy in specific biological processes (Table 1).

Structural Properties

Caspases are synthesized as enzymatically inactive precursors or zymogens, whereas a fully mature caspase enzyme is a tetramer comprising two large and two small subunits (McIlwain *et al.*, 2013). Pro-caspase zymogens consist of a C-terminal catalytic domain and an N-terminal prodomain (Figure 1; Kumar, 2007). The catalytic domains of caspases (where the active site resides) are comprised of a small and large subunit, both of which are required to achieve an enzymatically active conformation (Pop and Salvesen, 2009). The catalytic cysteine residue resides within the large subunit while the small subunit contains specific residues that are essential for structuring of the substrate-binding pockets and therefore are important for substrate recognition (Pop and Salvesen, 2009).

The prodomains of caspases differ with respect to their structure and function (Kumar, 2007; Pop and Salvesen, 2009). Apoptotic effector caspases (-3, -6, and -7) and caspase-14 contain very short prodomains, typically consisting of 20–30 amino acids (Figure 1). In contrast, the inflammatory and apoptotic initiator caspases have large (up to 220 amino acids) prodomains that contain homotypic protein–protein interaction motifs such as the caspase activation and recruitment domain (CARD) in caspase-1, -2, -4, -5, and -9 and the death effector domains (DEDs) in caspase-8 and -10 (Figure 1). These protein–protein interaction motifs of initiator caspases mediate their dimerization and recruitment into caspase activation complexes (see section Caspase Activation and Function in Cell Death and Inflammation; Kumar, 2007).

Non-Apoptotic Functions

Caspases were originally grouped based on studies demonstrating their functional role in specific biological process. However, many caspases have now been shown to be involved in processes that are distinct from their originally defined functions, blurring the lines between these functional classes (Miura, 2012). In addition to their well-characterized roles in apoptosis and cytokine maturation, caspases have been shown

Table 1 Phenotypes of caspase knockout mice

Caspase knockout	Mutant phenotypes	References
Caspase-1	Normal development, increased susceptibility to bacterial/viral infection, resistant to endotoxin shock, and impaired processing and secretion of inflammatory cytokines	Kuida <i>et al.</i> , 1995; Li <i>et al.</i> , 1995; Thomas <i>et al.</i> , 2009
Caspase-2	Normal development, increased number of oocytes, premature ageing-related traits, and slight growth retardation	Bergeron <i>et al.</i> , 1998; Shalini <i>et al.</i> , 2012
Caspase-3	Perinatal lethality (incomplete penetrance) in a mixed genetic background, neuronal cell death defects (brain hyperplasia), some cell types resistant to specific apoptotic stimuli	Kuida <i>et al.</i> , 1996; Woo <i>et al.</i> , 1998
Caspase-6	Normal development and no defects in apoptosis	McIlwain <i>et al.</i> , 2013
Caspase-7	Normal development and no defects in apoptosis	Lakhani <i>et al.</i> , 2006
Caspase-8	Embryonic lethality (complete penetrance), defects in death receptor-mediated extrinsic apoptosis, and impaired development of cardiac muscle and myeloid/lymphoid lineages	Salmena <i>et al.</i> , 2003; Varfolomeev <i>et al.</i> , 1998
Caspase-9	Perinatal lethality (incomplete penetrance), neuronal cell death defects (brain hyperplasia), and some cell types resistant to specific apoptotic stimuli	Hakem <i>et al.</i> , 1998; Kuida <i>et al.</i> , 1998
Caspase-11	Normal development, resistant to LPS-induced shock, impaired caspase-1-activation and IL-1 secretion	Wang <i>et al.</i> , 1998
Caspase-12	Normal development, resistant to sepsis and ER stress-induced apoptosis	Nakagawa <i>et al.</i> , 2000
Caspase-14	Normal development, impaired terminal differentiation of keratinocytes and increased sensitivity to UVB radiation-induced photodamage	Denecker <i>et al.</i> , 2007
Caspase-2/Caspase-9	Same as <i>Casp9</i> ^{-/-}	Marsden <i>et al.</i> , 2004
Caspase-3/Caspase-7	Perinatal lethality (complete penetrance) and resistant to intrinsic and extrinsic apoptosis	Lakhani <i>et al.</i> , 2006

Note: A summary of the development and phenotypes of caspase-deficient mouse strains. Note, there are no mouse homologs of caspase-5 and -10 and caspase-11 is the mouse homolog of human caspase-4.

Figure 1 Domain structure of human caspases. Schematic representation of the architecture of human caspases showing the prodomains and catalytic domain. The catalytic domain is comprised of a small and large subunit. Long prodomain-containing caspases contain protein–protein interaction motifs such as a CARD or DED. The caspases have been grouped according to their biological functions.

to participate in several biological processes via both cell autonomous and non-cell autonomous mechanisms (Miura, 2012). Studies in model organisms such as mice and *D. melanogaster* using genetic or pharmacological ablation of caspase activity have revealed these novel functions of the apoptotic caspases. For example, mice with T lymphocyte-specific disruption of caspase-8 display a reduction in mature T

lymphocytes and an attenuated immune response to viral infection (Salmena *et al.*, 2003). Interestingly, these defects in genetically modified mice are also recapitulated in humans harboring caspase-8 loss-of-function mutations who display attenuated activation and proliferation of T and B lymphocytes leading to immunodeficiency (Chun *et al.*, 2002). Moreover, perturbed proliferation has also been observed following

developmental apoptosis or wound healing upon inhibition of caspase activity (Huh *et al.*, 2004). Therefore, in addition to regulation of normal cell proliferation, caspases appear to be involved in compensatory proliferation under certain conditions.

More recently, it was shown that blocking caspase activity in *D. melanogaster* disrupts the pruning of neuronal dendrites and axons, a process which is critical for the formation of neural circuits (Williams *et al.*, 2006). These observations have also been extended in mouse models which demonstrate that caspases also appear to regulate synaptic plasticity in mammals (Nikolaev *et al.*, 2009). Furthermore, several reports have shown that caspases are also involved in the process of terminal differentiation in various progenitor cell types including myoblasts and monocytes (Fernando *et al.*, 2002; Sordet *et al.*, 2002). These studies demonstrate that caspases are important for programing and coordinating developmental events independently of their apoptotic functions.

Activation Mechanisms

Procaspase zymogens require enzymatic processing in order to achieve a mature, fully active tetrameric conformation. This requirement facilitates stringent regulation of caspase activity which is essential for preventing inappropriate triggering of the caspase cascade. Depending on the presence of protein–protein interaction motifs in their prodomain, different caspases are activated by distinct biochemical mechanisms.

Initiator Caspase Activation

Long prodomain-containing initiator caspases exist as inactive zymogen monomers in unstressed cells (Chai and Shi, 2014; Pop and Salvesen, 2009). The current model for activation of

initiator caspases is proximity-induced dimerization (Chai and Shi, 2014). According to this model, dimerization of initiator caspase zymogens occurs when they are brought into close proximity via recruitment into multimeric activation complexes (see section Caspase Activation and Function in Cell Death and Inflammation) resulting in high-local concentrations of zymogen monomers (Chai and Shi, 2014; Pop and Salvesen, 2009). These conditions favor dimerization which is thought to stimulate the catalytic activity and subsequent autoproteolytic cleavage between the small and large subunits of the catalytic domain (Figure 2; Chai and Shi, 2014; Pop and Salvesen, 2009). Homodimerization is believed to be the initial event that triggers activation of initiator caspases that mediate downstream signaling to effector molecules (Chai and Shi, 2014; Pop and Salvesen, 2009). Following autoproteolytic processing, the prodomains of initiator caspases are also removed by proteolysis to promote a mature enzyme conformation with full catalytic activity (Figure 2; Chai and Shi, 2014; Pop and Salvesen, 2009). Although the induced-proximity model is consistent with most biochemical data, it offers very little insight regarding the molecular mechanisms of initiator caspase activation under physiological conditions.

Effector Caspase Activation

In contrast to initiator procaspases, effector procaspases lacking long prodomains exist as inactive dimers in unstressed cells and have a much more well-characterized activation mechanism (Chai and Shi, 2014; Pop and Salvesen, 2009). Because they do not contain protein–protein interaction motifs, effector caspases rely on proteolytic cleavage by upstream initiator caspase for their activation. As with initiator caspases, interchain cleavage within the catalytic domain of effector caspases induces conformational rearrangements in the active site which greatly increases their catalytic activity (Figure 2; Chai and Shi, 2014; Pop

Figure 2 Caspase activation mechanisms. Depending on the structure of their prodomains, caspases are activated by different mechanisms. Long prodomain-containing initiator caspases exist as inactive monomers and are activated by proximity-induced dimerization which can sometimes be facilitated by adaptor proteins. Upon dimerization, interchain autocatalytic cleavage generates a catalytically activate enzyme. Further processing leads to the removal of the prodomain and formation of a mature tetramer assembled by the homodimerization of heterodimers. Effector caspases have short prodomains and exist as inactive dimers. They are activated by cleavage (mediated by activated initiator caspases) between the small and large subunits of the catalytic domain. As with initiator caspases, enzymatically active effector caspases are comprised of tetramers derived from two large and two small subunits.

and Salvesen, 2009). This is then followed by trimming of the prodomains of effector caspases to produce a fully mature enzyme conformation (Figure 2; Chai and Shi, 2014; Pop and Salvesen, 2009). Biochemical observations suggest that this final maturation event involving removal of prodomains is distinct from activation and is dispensable for acquisition of full catalytic activity (Chai and Shi, 2014; Pop and Salvesen, 2009). Moreover, crystal structures of mature initiator and effector caspases have revealed that enzymatically active caspase molecules exist as tetramers consisting of heterodimers of the small and large subunits of the catalytic domain, which assemble into homodimers (Figure 2; Chai and Shi, 2014; Pop and Salvesen, 2009).

Substrate Specificity and Targets

Biochemical Basis of Substrate Specificity

Caspases are defined as proteases that specifically cleave tetrapeptide substrates (P4-P3-P2-P1) C-terminal of a conserved aspartate residue (in the P1 position) using a cysteine-dependent catalytic mechanism (Poreba *et al.*, 2013). This stringent requirement for an aspartate residue in the P1 position of substrates is a characteristic biochemical property of the caspase family (Poreba *et al.*, 2013). All mammalian caspases also share a strong preference for glutamate residues in the P3 position of their substrates (Pop and Salvesen, 2009; Poreba *et al.*, 2013). Each amino acid in the tetrapeptide substrate (P1-P4) interacts with specific amino acid side chains that make up the corresponding substrate-binding pockets within the active site (named S4-S3-S2-S1) (Poreba *et al.*, 2013). The biochemical properties of these substrate-binding pockets define the specificity of each caspase. The S1 and S3 binding pockets are highly conserved between all caspases, with invariant amino acid residues in these pockets responsible for binding the conserved aspartate and glutamate residues in the P1 and P3 positions, respectively (Pop and Salvesen, 2009; Poreba *et al.*, 2013). Specificity in substrate recognition is endowed by virtue of the differential preferences of the P2 and P4 residues which is due to variability in the amino acids that make up S2 and S4 binding pockets (Pop and Salvesen, 2009; Poreba *et al.*, 2013).

Caspases belonging to the same functional classes share similar substrate recognition sequences (Table 2). This overlap in substrate preference between functionally related caspases may reflect functional redundancy between caspases that participate in the same biological processes. Given their overlapping substrate specificities, it is not surprising that caspases display a large degree of functional redundancy and are able to compensate for each other's functions (McIlwain *et al.*, 2013; Poreba *et al.*, 2013). Observations from caspase knockout mice clearly demonstrate this principle. For example, the caspase-3 substrate PARP is efficiently cleaved in caspase-3-deficient cells, suggesting that caspase-3 functions redundantly with other effector caspases, such as caspase-7 (Walsh *et al.*, 2008).

The optimal substrate recognition motif for the inflammatory caspases and caspase-14 is (W/L)EHD (Table 2; Benkova *et al.*, 2009; Mikolajczyk *et al.*, 2004). In contrast to these caspases which prefer hydrophilic or aromatic residues in the P4 position, apoptotic effectors caspase-3 and -7 have a

Table 2 Caspase substrate recognition motifs

Caspase	Substrate consensus motif (P5-P4-P3-P2-P1)	Known functions
1, 4, 5	(W/L) E X D	Inflammation
8, 9, 10, (6)	(I/V/L) E X D	Apoptosis initiation (execution)
3, 7	D E X D	Apoptosis execution
2	V D V A D	Apoptosis initiation/execution
14	W E H D	Keratinocyte differentiation

Note: The optimal substrate recognition sequence for human caspases, grouped according to their biological functions. Note the invariant aspartate residue in the P1 position (shown in bold). Proteolysis of substrates occurs immediately C-terminal of the P1 residue.

striking specificity for an aspartate residue in the P4 position of substrates (Table 2; Benkova *et al.*, 2009). Therefore, the optimal substrate recognition motif for caspase-3 and -7 is DEXD (Benkova *et al.*, 2009). Despite being functionally related to other effector caspases (-3 and -7), the optimal recognition sequence of caspase-6 is relatively less specific and resembles that of initiator caspases (-8, -9, and -10) which prefer the consensus motif (I/L/V)EXD (Table 2; Benkova *et al.*, 2009). Consistent with the biochemical properties elucidated from crystal structures, caspase-6 and the initiator caspases favor small, hydrophobic residues in the P4 position and show more flexibility in the P2 position, tolerating both hydrophobic and hydrophilic residues (Benkova *et al.*, 2009; Poreba *et al.*, 2013). Interestingly, the preferred substrate recognition motif for caspase-2 is unique among the caspase family. Unlike the other members of the caspase family which specifically cleave tetrapeptide motifs, caspase-2 has a strong preference for pentapeptide substrates (P5-P4-P3-P2-P1) with the consensus sequence VDVA D (Benkova *et al.*, 2009). *In vitro* biochemical studies show that caspase-2 has a weak affinity for DEVD substrates and that addition of an amino acid residue in the P5 position greatly enhances its catalytic activity (Benkova *et al.*, 2009; Tang *et al.*, 2011).

Caspase Substrates

Despite their specificity, a large degree of promiscuity exists between members of the caspase family. Overlapping substrate repertoires has hampered efforts to precisely define the contributions of individual caspases to specific biological processes (Poreba *et al.*, 2013). Furthermore, differences in endogenous expression levels and intrinsic catalytic activity of individual caspases have also been major obstacles to the identification of specific physiological caspase substrates *in vivo*.

Several hundred caspase substrates have been identified through biochemical and proteomic approaches. A list of caspase substrates can be found in databases such as CASBAH, CASVM, and PROSPER (see links to these databases at the end of this article). Caspase-3 is the most abundant effector caspase in cells and is responsible for cleaving most proteins that are associated with the onset of apoptosis (Poreba *et al.*, 2013). Cleavage by caspases can lead to either

inactivation or activation of substrates, however it remains unclear which of these cleaved proteins are *bona fide* caspase substrates with physiological relevance versus those that are innocent bystanders or artefacts of *in vitro* experimental systems. The most obvious targets of the initiator caspases are effector caspases, which, as discussed above require processing for activation (Pop and Salvesen, 2009). Cleavage of some caspase substrates is clearly linked to the characteristic morphological changes that take place in a cell undergoing apoptosis. For example, inhibitor of caspase activated DNase (ICAD) cleavage by caspase-3 permits activation of CAD which mediates cleavage of inter-nucleosomal linker DNA, producing characteristic DNA laddering that has been used as a marker for apoptosis for over 30 years (Enari *et al.*, 1998). In a recent finding, caspase-mediated cleavage and inactivation of the phospholipid flippase ATP11C was shown to be required for phosphatidylserine exposure which is necessary as an 'eat me' signal for engulfment of the apoptotic cells by macrophages (Segawa *et al.*, 2014). On the other hand, the inflammatory caspases mostly target pro-inflammatory cytokines for cleavage, so their activity is directly linked to their function in cytokine maturation and secretion (McIlwain *et al.*, 2013).

Caspase Activation and Function in Cell Death and Inflammation

Unlike other proteases that are involved in protein turnover and cleave a large number of proteins in a nonspecific manner, caspases function as important signaling enzymes that cleave specific repertoires of substrates which mediate downstream signaling events. Caspases have clearly defined and well-established functions in PCD and inflammation (McIlwain *et al.*, 2013). These processes are primarily controlled by upstream apical caspases whose activity is in turn regulated by specific activation complexes that assemble in response to specific stimuli (Chai and Shi, 2014). These activation complexes contain adapter proteins which recruit long prodomain-containing initiator caspases via conserved homotypic protein-protein interaction domains (see section Structure, Classification and Non-Apoptotic Biological Roles; Figure 1; Chai and Shi, 2014). These adaptor proteins serve as important molecular scaffolds that facilitate acquisition of an enzymatically active conformation by promoting autoproteolytic processing (see section Activation Mechanisms; Figure 2; Chai and Shi, 2014). The exact molecular details of the binding kinetics and stoichiometry of caspase activation platforms is still an active area of research. Hence, only the current dogma regarding assembly and function of these activation complexes is discussed here.

The Inflammasome (Inflammatory Response)

The inflammatory caspases (-1, -4, and -5) are important regulators of the inflammatory response, which plays a critical role in defense against infectious diseases as well autoimmunity and cancer (McIlwain *et al.*, 2013). In addition to noninfectious stimuli (e.g., tissue injury and environmental irritants), the inflammatory response can also be triggered by a vast range of infectious stimuli such as toxins and nucleic acids produced by

pathogenic bacteria, viruses, and fungi (McIlwain *et al.*, 2013). These pro-inflammatory stimuli are sensed by NOD-like receptor (NLR) proteins which belong to the family of highly conserved pattern recognition receptors (PRRs) that form an essential axis of the innate immune system (McIlwain *et al.*, 2013). To date, 23 NLR family members have been identified in the human genome, each of which recognizes specific repertoires of host- and pathogen-derived molecules referred to as damage-associated molecular patterns (DAMPs) and pathogen-associated molecular patterns (PAMPs), respectively (McIlwain *et al.*, 2013). In addition to NLR family members, other specialized PRRs such as the cytosolic double-stranded DNA sensor, AIM2 (absent in melanoma) can also initiate the inflammatory response (Hornung *et al.*, 2009). These specific sensory proteins initiate the assembly of multiprotein complexes called inflammasomes that activate caspase-dependent inflammatory signaling (Figure 3; Martinon and Tschopp, 2005).

Inflammasomes are multimeric protein complexes that serve as the activation platform for caspase-1, -4, and -5 in response to pro-inflammatory stimuli (Martinon *et al.*, 2002). Of the inflammatory caspases, caspase-1 is the most extensively studied in inflammasome signaling. Following recognition and binding to specific PAMPs or DAMPs, NLR or AIM2 monomers undergo conformational changes which promote their oligomerization and association with CARD-containing adaptor proteins such as apoptosis-associated speck-like protein containing a CARD (ASC) (Martinon *et al.*, 2002). This then facilitates CARD-dependent recruitment of procaspase-1 monomers, leading to their dimerization and autoproteolytic activation (Figure 3; Franchi *et al.*, 2009; Martinon *et al.*, 2002). The activity of caspase-1 is controlled by CARD-containing regulatory proteins such as COP and ICEBERG which are able to bind and sequester procaspase-1 monomers, inhibiting dimerization and autoproteolytic activation (Humke *et al.*, 2000; Lee *et al.*, 2001). Once activated, caspase-1 cleaves pro-IL-1 β and pro-IL-18, promoting their maturation and secretion (Figure 3; Franchi *et al.*, 2009; Martinon *et al.*, 2002). Upon secretion, these pro-inflammatory cytokines recruit and activate immune effector cells that drive the inflammatory response. Therefore, caspase-1-activation is crucial for initiating inflammation in response to injury or infection. The role of caspase-1 in innate immunity is further exemplified by caspase-1-deficient mice which show increased susceptibility to viral infection (Table 1; Thomas *et al.*, 2009).

Specificity in the inflammatory response is achieved by engagement of different sensory proteins (e.g., NLR family members) that recognize specific PAMPs or DAMPs and subsequently direct the assembly of different types of inflammasome complexes (McIlwain *et al.*, 2013). Therefore, the specific type of inflammatory stimulus a cell encounters, in addition to cell-specific expression of sensors and adapters, dictates which inflammasome complexes are assembled and therefore the downstream pathways that are engaged.

The Apoptosome (Intrinsic Apoptosis)

There are two distinct pathways that lead to apoptosis, namely the intrinsic (mitochondrial) pathway and the extrinsic (death receptor) pathway (see section The Death-Induced Signaling

Figure 3 Caspase activation platforms. Various multiprotein platforms have been described which promote activation of specific long prodomain-containing caspases. These multiprotein complexes contain a transducer that senses specific stimuli and adaptor proteins which recruit procaspase molecules via protein–protein interaction motifs in their prodomains. Intracellular stresses such as DNA damage and hypoxia trigger MOMP and subsequently activate the intrinsic apoptosis pathway and apoptosome formation while host and pathogen-derived pro-inflammatory stimuli trigger inflammasome formation. The extrinsic pathway of apoptosis is engaged upon DISC-mediated activation of caspase-8. Caspase-2 has been shown to be activated by the PIDDosome, however caspase-2 activation is also known to occur in the absence of PIDDosome. Assembly of these activation platforms and subsequent activation of apical caspases and downstream effectors ultimately lead to initiation of the inflammatory response or cell death.

Complex (Extrinsic Apoptosis); McIlwain *et al.*, 2013). The intrinsic pathway is activated by cellular stresses such as DNA damage and reactive oxygen species (McIlwain *et al.*, 2013). The stress signals trigger mitochondrial outer membrane permeabilization (MOMP), which causes the release of mitochondrial pro-apoptotic molecules such as cytochrome c (Kluck *et al.*, 1997). When released, cytochrome c associates with the adaptor protein apoptotic protease activating factor 1 (APAF-1) which exists in an auto-inhibited state in unstressed cells (Jiang and Wang, 2000). Analogous to formation of the NLR-ASC-caspase-1 inflammasome, this binding event causes a conformational change via an ATP-dependent mechanism that facilitates APAF-1 oligomerization and formation of a heptameric complex known as the apoptosome, which functions as an activation platform for procaspase-9 (Zou *et al.*, 1999; Figure 3). Binding of procaspase-9 monomers to the apoptosome (via CARD–CARD interactions between procaspase-9 and APAF-1) stimulates their proteolytic activity and subsequent activation by autoprocessing (Zou *et al.*, 1999).

Activated caspase-9 then processes the downstream effector caspases (caspase-3, -6, and -7), which in turn cleave other effector proteins (Figure 3; Zou *et al.*, 1999).

Activation of apoptotic caspases is tightly controlled by a network of pro-apoptotic and anti-apoptotic regulators that oppose each other's function. The balance between the activities of these regulators determines a cell's decision between survival and death. The pro-apoptotic Bcl-2 (B cell lymphoma 2) family proteins Bcl-2 homologous antagonist/killer (BAK) and Bcl-2-associated protein X (BAX) regulate MOMP which in turn controls cytochrome c release (McIlwain *et al.*, 2013). In response to intrinsic apoptotic stimuli, BAX and BAK oligomerize and form pores in the outer mitochondrial membrane (Wei *et al.*, 2001). Under basal conditions, BAK/BAX function is antagonized by anti-apoptotic members of the Bcl-2 family such as BCL-2 and BCL-XL, thereby inhibiting MOMP and blocking apoptosis (Fletcher *et al.*, 2008). Inhibition of apoptosis is also achieved by BCL-2-mediated neutralization of pro-apoptotic BH3 (Bcl-2 homology 3)-only proteins that

can directly activate BAK/BAX (Kuwana *et al.*, 2005). BH3-only proteins such as p53-upregulated modulator of apoptosis (PUMA) also regulate MOMP by sequestering anti-apoptotic Bcl-2 family members, thereby relieving inhibition of BAK/BAX (Chen *et al.*, 2005). Therefore, in mammalian cells, apoptosome assembly and subsequent caspase-9 activation is predominantly controlled by upstream Bcl-2 proteins that regulate MOMP.

In response to apoptotic stimuli, pro-apoptotic proteins can also promote caspase activation by inhibiting anti-apoptotic regulators and activating other pro-apoptotic effectors. One such pro-apoptotic factor released from mitochondria following MOMP is direct IAP-binding protein with low PI (DIABLO) (Verhagen *et al.*, 2000). DIABLO sequesters anti-apoptotic proteins of the inhibitor of apoptosis (IAP) family which, under basal conditions, block apoptosis by directly inhibiting caspase activation (Verhagen *et al.*, 2000). Interestingly, genetic deletion of *Drosophila* inhibitor of apoptosis 1 (DIAP1) in *Drosophila* is sufficient to trigger apoptosis via spontaneous activation of the effector caspase Drice (Wang *et al.*, 1999). Therefore, IAP proteins serve a much more important regulatory role in fruit flies compared to mammals in which intrinsic apoptosis is predominately controlled by Bcl-2 proteins.

Caspase-2 has been shown to be involved in intrinsic apoptosis induced by various types of stimuli, although the role of this caspase in most apoptotic pathways is considered to be redundant (Puccini *et al.*, 2013a). Like other initiator caspases, caspase-2 cleavage can be facilitated by a multi-protein activation complex. This caspase-2 activation platform, termed the PIDDosome, consists of procaspase-2 complexed with p53-induced death domain protein (PIDD) and the adaptor molecule RIP-associated protein with a death domain (RAIDD) (Tinel and Tschopp, 2004). RAIDD recruits procaspase-2 via CARD–CARD interactions and subsequently associates with PIDD in a death domain (DD)-dependent manner leading to formation of the PIDDosome (Tinel and Tschopp, 2004). Although biochemical observations demonstrate that the PIDDosome can catalyze caspase-2 autoactivation, *in vitro* studies and *in vivo* evidence from knockout mice indicates caspase-2 activation can occur independently of RAIDD and PIDD, challenging the physiological relevance of the PIDDosome in caspase-2 activation (Baliga *et al.*, 2004; Manzl *et al.*, 2009; Read *et al.*, 2002). Regardless of its mechanism of activation, caspase-2 has been implicated in many processes including tumor suppression, ageing, and maintenance of genomic stability (Ho *et al.*, 2009; Puccini *et al.*, 2013b; Shalini *et al.*, 2012). However, it remains to be established whether some or any these functionalities of caspase-2 are dependent on its function in PCD.

The Death-Induced Signaling Complex (Extrinsic Apoptosis)

The extrinsic pathway of apoptosis is a critical component of the immune system that is required for the removal of damaged or infected cells (Walczak, 2013). The extrinsic pathway is engaged upon binding of extracellular ligands to transmembrane death receptors (Walczak, 2013). Several types of death receptors (e.g., Fas and TNFR) and ligands (e.g., FasL and TNF α) have been identified which belong to the tumor

necrosis factor super family (TNFSF) (Walczak, 2013). Each death receptor has cognate death ligands and specific adaptor molecules which facilitate the assembly of specific intracellular signaling complexes (Walczak, 2013). Therefore, different combinations of death ligands and adaptors give rise to specificity in death receptor signaling. In addition to the ligand binding domain in their extracellular region, death receptors contain DDs in their intracellular tails that allow interactions with DD-containing adaptor molecules (Walczak, 2013). Ligand binding stimulates the oligomerization of death receptors at the plasma membrane (e.g., Fas–FasL interaction) leading to the formation of homotrimeric death receptor complexes (Walczak, 2013). Adaptor molecules such as Fas-associated protein with death domain (FADD) are then recruited to the intracellular DDs of specific death receptor complexes (Chinnaiyan *et al.*, 1995). These adaptor molecules also contain DEDs which recruit DED-containing initiator caspases (such as procaspase-8) stimulating the formation of the death-induced signaling complex (DISC) and their activation by dimerization-dependent autoprocessing (Figure 3; Medema *et al.*, 1997). A recently proposed model suggests that DISC-mediated caspase-8 activation can also occur by a novel mechanism in which procaspase-8 monomers assemble into chain structures via DED–DED interactions (Dickens *et al.*, 2012). In addition to downstream effector caspases, activated caspase-8 can also cleave BH3 interacting-domain death agonist (BID) (Li *et al.*, 1998). This results in a truncated form of BID (tBID) that is capable of interacting with BAK/BAX, thereby stimulating MOMP and triggering procaspase-9 activation (Li *et al.*, 1998). Through this mechanism, death receptor-mediated activation of BID provides a connection between the intrinsic and extrinsic pathways.

As with other caspase activation platforms, the activity of the DISC is controlled by a host of regulatory proteins. One such well-characterized regulator of DISC assembly and extrinsic apoptosis is flc-like inhibitory protein (FLIP) (Irmeler *et al.*, 1997). FLIP contains two DEDs which compete with procaspase-8 for FADD binding and recruitment into the DISC (Irmeler *et al.*, 1997). Therefore, FLIP can act as an anti-apoptotic decoy caspase that limits procaspase-8 activation.

New Modes of Caspase-Regulated Cell Death

Over the last two decades, research on caspases has largely focused on their role as regulators of inflammation and apoptosis. More recently however, alternative modes of caspase-regulated PCD have come to light.

Pyroptosis

In addition to regulation of the inflammatory response (see section The Inflammasome (Inflammatory Response)), caspase-1-activation can also lead to cell death by a process called pyroptosis. Pyroptosis was originally described in bacteria-infected macrophages and characterized by morphological features including membrane swelling and rupture leading to the release of pro-inflammatory cell contents (Zychlinsky *et al.*, 1992). The definition of pyroptosis has since been refined to

describe a mode of caspase-1-dependent inflammatory cell death whose function is not limited to bacterial infection or macrophages (Galluzzi *et al.*, 2012). Therefore, pyroptosis has been suggested to represent a mechanism of crosstalk between inflammation and cell death, serving as a defense strategy against damaged or pathogen-infected cells. In support of this concept, various bacteria and viruses have evolved mechanisms to suppress inflammation and evade inflammatory cell death by expressing proteins that inhibit caspase-1 signaling (Galluzzi *et al.*, 2012).

Pyroptotic and apoptotic cells share some morphological features such as nuclear condensation and DNA fragmentation (Galluzzi *et al.*, 2012). However, unlike apoptotic cell death that involves degradation of internal cellular components without compromising membrane integrity, cell demise by pyroptosis occurs by osmotic lysis and release of intracellular contents (Galluzzi *et al.*, 2012). Although the morphological features of pyroptotic cell death were described almost two decades ago, the molecular events associated with this mode of cell death are poorly defined. As with initiation of the inflammatory response, pyroptosis is associated with inflammasome-dependent caspase-1 activation and processing and secretion of pro-inflammatory cytokines (IL-1 β and IL-18) (Figure 3; Galluzzi *et al.*, 2012). Under certain conditions during inflammation, secretion of these pro-inflammatory cytokines coincides with caspase-1-mediated cleavage and activation of the effector caspase, caspase-7 but not caspase-3 (Miao *et al.*, 2011). However, given that cytokine secretion and caspase-7 activation have been shown to be dispensable for caspase-1-mediated cell death, the physiological relevance of these factors to inflammatory cell death is not well understood (Miao *et al.*, 2011). Furthermore, the downstream effectors of caspase-1 that are required for pyroptosis remain largely unknown.

Recently, a novel role for inflammatory caspases-4 and -5 in pyroptosis induced by bacterial lipopolysaccharide (LPS) was described (Shi *et al.*, 2014). In this study, caspase-4 and -5 were shown to be able to directly bind LPS with high affinity (Shi *et al.*, 2014). This interaction triggered CARD-dependent oligomerization and activation of these inflammatory caspases leading to pyroptosis (Shi *et al.*, 2014). These findings revealed a previously uncharacterized mechanism of caspase activation and demonstrate that caspases not only serve as the initiators of downstream signaling following infection but can also function as pattern recognition molecules in the innate immune response. Although pyroptosis is characterized by specific morphological features and signaling events that are distinct from apoptosis, whether pyroptosis actually represents a *bona fide* mode of non-apoptotic, caspase-dependent cell death *per se*, or is simply an alternative channel of apoptotic cell death in response to pro-inflammatory or infectious stimuli is still a matter of debate. Moreover, the mechanisms and stimuli that govern the decision between pro-survival (inflammation) and pro-death (pyroptosis) outcomes in response to inflammatory stimuli is still an active area of research.

Necroptosis

Until recently, necrosis was viewed as a route of passive cell death that occurred in an unordered, random manner in

response to injury. However, pioneering work from various groups has provided clear evidence that necrosis can proceed in a highly ordered manner through well-defined molecular pathways that are genetically regulated. This type of regulated necrotic cell death is now referred to as programmed necrosis or necroptosis.

Necroptosis was originally identified as a mode of cell death induced by TNF in the presence of a pan-caspase inhibitor (Vercammen *et al.*, 1998). As discussed in section The Death-Induced Signaling Complex (Extrinsic Apoptosis), it is well-established that death ligands such as TNF induce apoptosis through a caspase-dependent pathway. These observations demonstrated that TNF was able to induce necrotic-like cell death in the absence of caspase activity. It is now well-recognized that caspases are intrinsic suppressors of necroptosis. Therefore, in stark contrast to apoptosis, necroptosis occurs in a caspase-independent manner and results in cell demise that is more akin to inflammatory cell death characterized by membrane rupture, cell swelling and lysis (Vanden Berghe *et al.*, 2014). However, it is now clear that many components of apoptotic pathways also have important regulatory functions in necroptosis signaling, suggesting that crosstalk mechanisms occur between these two apparently distinct modes of cell death.

Like inflammation, necroptosis plays an important role in innate immunity by activating various pro-inflammatory pathways in response to infection but can also have deleterious, pathological effects under certain conditions. Many viruses have evolved mechanisms that promote immune evasion and destruction. One such mechanism is the expression of virally-encoded caspase inhibitors (e.g., vFLIP) that are potent suppressors of apoptosis during infection (Thome *et al.*, 1997). Therefore, necroptosis may have evolved as a backup mechanism of PCD in vertebrate immune systems that operates to ensure cell demise when caspases activity is inhibited by invading pathogens (Vanden Berghe *et al.*, 2014).

Many different types of stimuli have been shown to trigger necroptosis including ligation of various death ligands (e.g., Fas and TNF), tissue injury, cytotoxic drugs, and infection (Vanden Berghe *et al.*, 2014). Regardless of the type of stimuli a cell encounters, engagement of the necroptotic pathway converges on stabilization and activation of receptor-interacting protein kinase 1 (RIPK1) and RIPK3 (Vanden Berghe *et al.*, 2014). Depending on the nature of the upstream signal, RIPK1 and RIPK3 associate with different regulatory factors that ultimately lead to activation of downstream effectors (Vanden Berghe *et al.*, 2014). Necroptosis induced by TNF is the most extensively studied necroptotic pathway to date. As discussed in section The Death-Induced Signaling Complex (Extrinsic Apoptosis), in response to death receptor engagement in caspase-8-proficient cells, caspase-8 is recruited to adaptor proteins such as FADD and activated by the DISC. Under these conditions, active caspase-8 directly cleaves and inactivates RIPK1 and RIPK3, thereby inhibiting necroptosis (Lin *et al.*, 1999; Oberst *et al.*, 2011). However, under conditions of caspase-8 inhibition (such as expression of virus-derived caspase inhibitors) or in caspase-8-deficient cells, RIPK1 and RIPK3 are stabilized. RIPK1 and RIPK3 activate each other and themselves by trans- and auto-phosphorylation and form a multiprotein complex called the necrosome (Cho *et al.*, 2009; Li *et al.*, 2012). Once activated in

the necrosome, RIPK1 and RIPK3 phosphorylate and activate downstream effectors, such as MLKL, that execute necroptosis (Sun *et al.*, 2012).

In summary, since the discovery of the first caspase CED-3 as a mediator of PCD, caspases have established themselves as critical enzymes that not only initiate and execute apoptosis, but play many roles in various biological processes such as immunity, inflammation, differentiation, and development. While much of the mechanistic insight into caspase enzymology and substrate cleavage is now established, the mechanisms of initiator caspase activation *in vivo* remain to be fully elucidated. Another gap in our knowledge is how many and which substrates need to be cleaved by caspases in order to ensue apoptosis. The emerging non-apoptotic and pleiotropic functions of caspases, not extensively covered in this article, suggest that targeting caspases in the treatment of diseases is far more complex than originally envisaged. On the other hand, the extensive knowledge of caspase biology and function may provide opportunities to target caspases in specific pathologies.

Acknowledgments

The caspase and cell death studies in our laboratory are supported by the National Health and Medical Council of Australia project grants (1021456, 1041807, and 1043057) and fellowship (1002863). We apologize to colleagues whose primary publications could not be cited due to the editorial policy on the number of references that can be included in this article.

Glossary

Efferocytosis The process by which a phagocyte engulfs a neighboring cell that is in early stages of cell death.

Postpartum breast cancer Breast cancers that are diagnosed in premenopausal women 2–5 years following a full-term pregnancy.

Postpartum involution Widespread cell death of the milk-producing epithelium of the breast, followed by structural remodeling of mammary microenvironment.

Introduction

Cells in the body are constantly being ‘turned over,’ to remove aged, damaged, or functionally unnecessary cells. Injury, pathogens, and physiological cues can induce widespread cell death in a tissue. For example, the milk-producing cells of the breast die when nursing ceases, while chemotherapeutic treatment of cancers would induce a profound burden of tumor cells. Regardless of the cause or extent of cell death, it is important that dying cells are rapidly removed, to prevent dying cells from releasing intracellular antigens that might trigger inflammation, tissue damage, or autoimmunity. Clearance of dying cells also stimulates production of cytokines and growth factors, that enhance cell growth and wound healing, and that dampen tissue-damaging immune responses. Given the profound burden of dying cells in the post-lactational breast, the breast is especially adept at clearance of dying cells during postpartum involution. Dying cells are removed from the breast by a process called ‘efferocytosis,’ wherein macrophages or phagocytic mammary epithelial cells engulf the dying cell. Efferocytosis is the body’s natural response to dying cells, aimed at suppressing immune responses and promoting tissue repair. Following efferocytosis, macrophages produce wound healing cytokines, adopt M2-like macrophage markers associated with wound healing, present antigens, promote immune tolerance, and dampen cytotoxic immunity. Macrophages use a cell surface protein called MerTK to recognize and engulf dying cells. The receptor tyrosine kinase (RTK) MerTK is critical for efferocytosis by wound-associated macrophages and for the cytokine modulation that follows.

A Historical Overview of Efferocytosis

Cell death occurs within most multicellular organisms. The idea that cell death within a developing or mature organism generally requires removal of those dying cells to maintain tissue homeostasis was noted more than 100 years ago when Metchnikoff coined the term ‘physiologic inflammation’ (Tauber, 2003). Since then, vast research into programmed cell death demonstrates the unique cellular packaging of dying cells into apoptotic bodies, such that the dying cell’s contents are encased within a plasma membrane that is flagged for clearance. This ensures that the intracellular contents are not

leaked into the immediate environment, which could potentially trigger immune reactions against these cellular contents. Earlier work in nematodes and mammals clearly demonstrated that apoptotic bodies were removed locally in tissues by ‘silent’ processes that did not induce inflammation, involving the uptake of apoptotic bodies by neighboring cells (Ellis *et al.*, 1991; Reddien and Horvitz, 2004; Walsh *et al.*, 1999). Since these early studies, it has become clear that all multicellular organisms, including humans, have conserved processes to engulf apoptotic bodies. Apoptotic cells are engulfed and digested by phagocytes, such as macrophages and dendritic cells (the ‘professional phagocytes’) (Fadok *et al.*, 1992; Rothlin *et al.*, 2007; Hu *et al.*, 2000). Increasing evidence suggests that many cell types in the body, including epithelial cells and fibroblasts, are capable of engulfing dying cells (Henson *et al.*, 2001; Henson and Hume, 2006; Monks *et al.*, 2008; Vandivier *et al.*, 2006; Prasad *et al.*, 2006), although nonprofessional phagocytes engulf dying neighbors with decreased efficiency as compared to macrophages and dendritic cells.

Since phagocytosis of dying cells was found to suppress inflammation, the term ‘physiological inflammation’ was revisited in an effort to reflect more accurately this process. Further, the term phagocytosis was too broad, given the many types of phagocytosis being recognized, with phagocytic clearance of dying cells using a distinct signaling pathways and producing distinct morphological features versus other modes of phagocytosis. Based on these observations, Henson and colleagues proposed the term ‘efferocytosis’ (taken from the Latin *effero*, meaning ‘to take to the grave’ or ‘to bury’) to indicate the specialized process by which phagocytic cells engulf dying cells and then modulate cytokines to dampen acute inflammation (Henson *et al.*, 2001; Henson and Hume, 2006). From these early beginnings, the importance of efferocytosis in homeostasis of multiple tissues has been explored. Additionally, new roles for efferocytosis have been discovered, including the impact of efferocytosis on intracellular microbes, antitumor immunity, and autoimmunity.

Efferocytosis Is an Established Process That Is Rapidly Deployed in the Breast

The breast endures vast changes during reproductive phases of a woman’s life (puberty, pregnancy, lactation, postpartum

Figure 1 Schematic depicting efferocytosis during postpartum involution, and how this affects the breast microenvironment. Our hypothesis predicts that efferocytosis-induced cytokines will modulate leukocyte populations to increase tumor malignancy following episodes of widespread tumor cell death in response to postpartum involution. AC, apoptotic/dying cell; CD4, CD8, T-cells; M2, M2 macrophages.

involution, and postmenopausal involution). Although much of the patterning of the mammary ductal tree occurs during puberty, growth of milk-producing mammary epithelial cells occurs mainly during pregnancy, expanding mammary epithelial content by as much as 10-fold. Once offsprings are weaned, milk-producing mammary epithelial cells undergo rapid and widespread cell death (Figure 1), removing up to 90% of the total mammary epithelial content within the time span of just 1 week in rodent models. This returns the mammary gland to an almost pre-pregnant state, so that the changes in the mammary gland that accompany pregnancy, lactation, and involution may again occur with each successive pregnancy.

Involution of the post-lactational breast (or the postpartum breast, in the absence of nursing) is remarkable in terms of the robust burden of dying epithelial cells that require clearance. This makes the postpartum breast ideal for studying phagocytic engulfment of dying cells, or 'efferocytosis.' Efferocytosis dampens acute inflammatory responses upregulates tolerogenic cytokines and leukocytes, and promotes tissue repair and regrowth (Figure 1). In the absence of efferocytosis, dying cells undergo secondary necrotic lysis, often producing acute inflammation and immunity against self-antigens.

Efferocytosis is frequently performed by 'professional phagocytes' (macrophages and dendritic cells) but epithelial cells are also capable of efferocytosis under certain conditions. For example, mammary epithelial cells are capable of engulfing dying mammary epithelial cells during postpartum involution (Monks *et al.*, 2005, 2008; Sandahl *et al.*, 2010), although numerous bone marrow and spleen-derived macrophages are recruited to the postpartum breast in response to a growing burden of dying cells during early involution. Soluble chemo-attractants, or 'find me' signals such as monocyte chemo-attractant protein-1 (MCP-1/CCL2), CX3CL1, CCL6, CCL7, CCL8, and CXCL14, are released from dying cells during early involution (Nagaosa *et al.*, 2003), which may draw macrophages into the postpartum mammary gland (Graham *et al.*, 2011; Truman *et al.*, 2008; Clarkson *et al.*, 2004; Stein *et al.*, 2004).

Once recruited, the macrophages (or other phagocytes) identify dying cells in the local environment by engaging cell death signals that are specific to dying cells, often referred to as 'eat me' signals. External phosphatidylserine (PS) exposure is a

well-recognized marker of dying cells. Although PS is maintained on the inner plasma membrane leaflet in most healthy cells, externalized PS is how a dying cell signals to phagocytes for its engulfment (Fadok *et al.*, 1992; Borisenko *et al.*, 2003; Martin *et al.*, 1995). Externalized PS often is recognized directly by receptors, such as PS receptor (PSR), stabilin-2, TIM family receptors, and brain angiogenesis inhibitor 1 (BAI1), expressed on the surface of the phagocyte (Luciani and Chimenti, 1996; Mani *et al.*, 2010; Park *et al.*, 2007, 2008a,b; DeKruyff *et al.*, 2010; Ichimura *et al.*, 2008; Kobayashi *et al.*, 2007; Miyanishi *et al.*, 2007; Rodriguez-Manzanet *et al.*, 2010; Santiago *et al.*, 2007; Wong *et al.*, 2010). Other receptors bind to PS through extracellular bridging molecules, such as milk fat globule-epidermal growth factor-like 8 (MFG-E8), growth arrest-specific gene 6 (Gas6), Tubby, Tubby-like Protein-1 (TLP1), and Protein S, that simultaneously binds PS and the receptor (Hanayama *et al.*, 2002, 2004; Akakura *et al.*, 2004; Nakano *et al.*, 1997; Ishimoto *et al.*, 2000; Hall *et al.*, 2005). Receptors that bind to bridging molecules include MerTK, Axl, Tyro3, $\alpha\beta3$, and $\alpha\beta5$ integrins. Once the dying cell is engaged either directly or through a bridging molecule to receptors on the phagocyte, intracellular signaling events promote actin reorganization and phagocytic ingestion. The CrkII-DOCK180-ELMO complex activates Rac GTPase signaling to produce actin-dependent membrane extensions that physically engulf the target cell (Reddien and Horvitz, 2000; Gumieny *et al.*, 2001; Hasegawa *et al.*, 1996; Kiyokawa *et al.*, 1998; Van Aelst and D'Souza-Schorey, 1997), while RhoA counters the actin remodeling required for efferocytosis (Nakaya *et al.*, 2006; Riento and Ridley, 2003). Once engulfed, the dying cell is dispatched by the efferocyte, primarily through lysosomal degradation.

Although macrophages are professional phagocytes/efferocytes, mammary epithelial cells are capable of efferocytosis at the earliest stages of postpartum involution, ensuring a rapid response to the massive level of apoptosis that occurs during early involution, prior to peak accumulation of macrophages during this highly dynamic phase. Gas6-MerTK signaling is critical for mammary epithelial cell-mediated efferocytosis during post-lactational involution, as is MFG-E8, presumably through $\alpha\beta3$ and/or $\alpha\beta5$ integrins, although this has not yet been demonstrated (Sandahl *et al.*, 2010). However, the integrins $\alpha\beta3$ and $\alpha\beta5$ are expressed in the early

post-lactational mammary epithelium, when MFG-E8 is induced (Oshima *et al.*, 2002; Nakatani *et al.*, 2006; Hanayama and Nagata, 2005).

Following efferocytosis, transcriptional events in the efferocyte modulate cytokine expression in the local microenvironment (Figure 1), which orchestrate a wound healing, angiogenesis, and dampening of acute or cytotoxic inflammation (Silva, 2010). Wound healing expression signatures are robustly produced during postpartum involution (Monks *et al.*, 2005; O'Brien and Schedin, 2009; Stein *et al.*, 2004, 2009; Atabai *et al.*, 2007; Deonaraine *et al.*, 2007), consistent with transcriptional changes following efferocytosis. Recent studies demonstrate the critical nature of efferocytosis in the postpartum breast. Macrophages in MerTK-deficient mice are incapable of efferocytosis. Although mammary development occurs normally through puberty, pregnancy, and lactation in MerTK-deficient mice, impaired efferocytosis during postpartum involution allowed for secondary necrosis of mammary epithelial cells, impaired wound healing and cytokine modulation, caused inflammation and scarring, and interfered with lactation in future pregnancies (Sandahl *et al.*, 2010). Similar findings were seen upon loss of MFG-E8 signaling in the postpartum mammary gland (Hanayama and Nagata, 2005; Nakatani *et al.*, 2006). These findings underscore the need for rapid clearance of dying cells during postpartum involution.

Efferocytosis in the Tumor Microenvironment

Similar to what is seen in healthy breast, cell death is a feature of all breast tumors, but very little is known regarding efferocytosis-induced wound healing in breast cancers. Further parallels exist between sterile wounds and tumors beyond locally increased cell death, as both wounds and tumors are characterized by an abundance of M2 macrophages that express high levels of MerTK, a macrophage phenotype associated with efferocytosis (Zizzo *et al.*, 2012). Efferocytosis in the mammary tumor microenvironment heightens both MerTK expression and M2 polarization of tumor-associated macrophages (Figure 1), causing increased expression of immune suppressive Th2-like cytokines such as IL-4, IL-10, IL-13, and transforming growth factor (TGF)- β (De Oliveira Fulco *et al.*, 2014). In clinical breast cancer datasets, Th2 cytokines and M2 macrophages each correlate with decreased overall survival (Kristensen *et al.*, 2012). Consistent with this observation, tumor metastasis was increased following the induction of cell death and efferocytosis in the tumor microenvironment during postpartum/post-lactational involution, whereas inhibition of efferocytosis (through pharmacological or genetic MerTK inhibition), or inhibition of efferocytosis-induced cytokines TGF- β or IL-10 resulted in decreased distant tumor metastasis (Stanford *et al.*, 2014). These data demonstrate a mechanistic link in the tumor microenvironment between tumor cell death, efferocytosis, M2 macrophage activity, and metastasis. The precise mechanisms by which efferocytosis promotes tumor metastasis is unclear. Further investigations will fill this knowledge gap, clarifying how dynamic changes in the tumor microenvironment support tumor metastasis, and how we can combat tumor metastasis and recurrence through therapeutic strategies aimed at efferocytosis and efferocytosis-induced

cytokines. However, malignant tumor progression has long been compared to the wound healing process, due to the elevated rate of cell death, the presence of M2 macrophages, and expression of immunosuppressive cytokines. Interestingly, these same attributes characterize the post-lactational mammary gland.

Efferocytosis and Postpartum Breast Cancer

Although pregnancy at a young age decreases lifetime breast cancer risk, the first 5 years following pregnancy are associated with 'increased' breast cancer risk regardless of the woman's age, and with even greater risk with increasing age at the woman's first pregnancy. Increasingly, women are postponing child-birth, which may increase the incidence of postpartum breast cancer, defined as those breast cancers diagnosed 2–5 years after pregnancy. Currently, postpartum breast cancer accounts for nearly 25% of all breast cancers in young (premenopausal) women (Callihan *et al.*, 2013; Martinson *et al.*, 2013). In contrast to breast cancers diagnosed 'during' pregnancy, which correlate with a favorable prognosis, postpartum breast cancers are highly aggressive, more likely to be diagnosed at a metastatic stage, and display profoundly reduced 5-year survival (Lyons *et al.*, 2009; Martinson *et al.*, 2013, 2015). A series of studies in which breast cancer cells were injected into the mammary fat pads of age-matched female mice that were either never pregnant or that were at involution day 1 revealed the profound influence of postpartum involution on the capacity for the mammary microenvironment to promote malignant tumor progression (Lyons *et al.*, 2011, 2014; Maller *et al.*, 2013; Martinson *et al.*, 2015; McDaniel *et al.*, 2006; Schedin, 2006, 2007; Schedin and Borges, 2009). Detailed analysis of the postpartum breast and tumor microenvironment identified key roles played by M2 macrophages in establishing and maintaining the pro-tumor microenvironment, such as collagen grooming and cytokine regulation (Lyons *et al.*, 2011; O'Brien *et al.*, 2010, 2012; O'Brien and Schedin, 2009).

Using mouse models of postpartum breast cancer to compare mammary tumor progression in nulliparous (virgin) mice to those in age-matched but parous (single pregnancy), it was discovered that tumors from parous mice harvested during postpartum involution, but not during pregnancy, are 10-fold more metastatic, and expressed higher levels of wound healing cytokines and harbored more intra-tumoral M2 macrophage markers (Stanford *et al.*, 2014). These are the same pathological traits seen in human postpartum breast cancers (Borges and Schedin, 2012; Fornetti *et al.*, 2014). Studies have shown that widespread cell death, the hallmark of postpartum involution, triggers macrophage-mediated efferocytosis, M2 macrophage polarization, wound healing cytokine production, and TGF β -mediated tumor cell invasion in postpartum breast cancers (Stanford *et al.*, 2014). However, genetic or pharmacological MerTK inhibition impaired efferocytosis in postpartum breast cancers, blocking macrophage M2 polarization, expression of wound healing cytokines, and repressing formation of lung metastases. These findings support the idea that efferocytosis enhances metastasis of postpartum breast cancers.

Conclusion and Future Directions

Taken together, these collective findings suggest that clearance of dying cells is advantageous in sterile wounds, such as the postpartum mammary gland, for epithelial regrowth and repair, but this same process in the context of the breast tumor microenvironment may promote tumor growth and malignancy. These studies suggest that efferocytosis is a targetable process through use of MerTK-directed inhibitors, which potentially could improve the outcome for young women diagnosed with postpartum breast cancer. It remains unclear if efferocytosis-induced wound healing and metastatic acceleration similarly occurs in response to chemotherapy-induced tumor cell death. Therefore, future studies investigating efferocytosis-induced wound healing in the tumor microenvironment could have a substantial impact throughout the wider cancer research field, and may identify an opportunity to improve efficacy of currently used therapeutics that trigger widespread tumor cell death.

The Bcl-2 Family Proteins: Insights into Their Mechanism of Action and Therapeutic Potential

DW Andrews and H Brahmabhatt, Sunnybrook Research Institute, Toronto, ON, Canada

Apoptosis and the Bcl-2 Family: A Historical Perspective

Apoptosis was first described in 1972 as a controlled form of programmed cell death distinct from necrosis that is required during development and in the maintenance of homeostasis of multi-cellular organisms (Kerr *et al.*, 1972). In 1985, the gene encoding B-cell lymphoma-2 (Bcl-2), the founding member of the family, was identified from a follicular lymphoma patient where a chromosomal translocation t(14;18) resulted in dysregulated Bcl-2 expression (Tsujimoto *et al.*, 1985). The link between Bcl-2, apoptosis, and cancer was established when the BCL-2 gene product was shown to block cell death rather than to enhance cell proliferation as was expected as the mode of action of oncogenes at that time (Vaux *et al.*, 1988; Hockenbery *et al.*, 1990). This seminal observation led to the concept that impaired apoptosis was critical for tumorigenesis (Hanahan and Weinberg, 2000).

The Pathway of Apoptosis

Cellular signals that initiate apoptosis originate from many different types of intracellular stresses such as DNA damage and the unfolded protein response (UPR), or from external signals like the engagement of extracellular death receptors by ligands such as binding of tumor necrosis factor alpha (TNF α) or Fas to their cognate receptors on cancer cells (Fulda and Debatin, 2006). While both these cell intrinsic and extrinsic pathways are regulated by the Bcl-2 family of proteins, the former is more tightly regulated by the Bcl-2 family proteins because these apoptotic signals ultimately converge to cause mitochondrial outer membrane permeabilization (MOMP). As a consequence of MOMP, factors such as cytochrome c are released from the mitochondrial intermembrane space into the cytoplasm, which leads to the activation of a cascade of proteases termed caspases that cleave a distinct population of subcellular substrates that yields the characteristic apoptotic phenotype (Garrido *et al.*, 2006; Chipuk *et al.*, 2006). Therefore by initiating this final effector phase of apoptosis MOMP is typically regarded as the point of no return for a cell. The crucial role of Bcl-2 family of proteins is to regulate MOMP by a coordinated series of protein–protein and protein–membrane interactions (Leber *et al.*, 2010, 2007).

The Bcl-2 Family of Proteins: Classification and Structure

More than 20 Bcl-2 family proteins have been identified and are classified into three groups based on function and sequence similarity within four conserved Bcl-2 homology (BH) regions (Figure 1(a); Sato *et al.*, 1994). The first group

comprises the anti-apoptotic proteins, Bcl-2, Bcl-XL, Bcl-w, Mcl-1, and AL, which contain all four BH regions. The pro-apoptotic family members are distributed in two groups: (1) Bax and Bak, the proteins that form the pore in the mitochondrial outer membrane to mediate MOMP share sequence similarity in the BH1-3 regions and a modified BH4 region, and (2) the BH3 proteins such as Bid, Bim, Puma, Bad, Noxa, Bmf, Bik, Beclin-1 and Hrk which function as stress sensors and only share homology in the BH3 region (Kvansakul *et al.*, 2008). A feature found in many Bcl-2 family proteins is a carboxyl-terminal (C-terminal) transmembrane region (TM) which anchors proteins to intracellular membranes such as the mitochondrial outer membrane (MOM), endoplasmic reticulum (ER) and nucleus (Shamas-Din *et al.*, 2013b).

Although Bcl-2 family proteins vary in function and in amino acid sequence, the multi-region Bcl-2 family proteins show a similar structural fold thus providing insights into binding interactions that explains their mechanism of action. The three-dimensional solution structures show a common fold where two central hydrophobic α -helices form a hairpin surrounded by 6–7 amphipathic α -helices. Additionally, a long unstructured flexible loop is present between helix 1 and helix 2. The loop acts as a regulatory region and is sensitive to posttranslational modifications. The BH1-3 regions form a hydrophobic groove of different sizes (Petros *et al.*, 2004), and these grooves serve as the docking sites for specific BH3 regions of other Bcl-2 family members in a fashion analogous to ligand-receptor interactions (Figure 1(b); Sattler *et al.*, 1997; Petros *et al.*, 2000; Liu *et al.*, 2003; Czabotar *et al.*, 2013; Dewson *et al.*, 2008). In Bax and Bcl-w, the hydrophobic C-terminal TM region occludes the hydrophobic groove from the aqueous environment of the cytoplasm (Suzuki *et al.*, 2000; Denisov *et al.*, 2003).

In contrast to the multi-region Bcl-2 proteins, NMR studies of Bim, Bad, Bmf and sequence analysis of BH3 proteins other than Bid and Bik suggest that they are intrinsically unstructured, but that the BH3 region becomes structured after interaction with the binding groove in anti-apoptotic members (Hinds *et al.*, 2007). Bid is an exception as it has a defined structure similar to the multi-region members, rather than its BH3 protein counterparts (Shamas-Din *et al.*, 2013a; Billen *et al.*, 2008b). From an evolutionary perspective, the multi-region Bcl-2 family members and Bid share a common ancestral origin whereas the BH3 proteins evolved later and separately (Aouacheria *et al.*, 2005). There is no structural information available for Bik but sequence analysis suggests that it may also be an all helical protein similar to the multi-region Bcl-2 family proteins. Unlike other family members, several BH3 proteins appear to have functions unrelated to apoptotic activity or to the functions of other BH3 proteins.

Figure 1 Schematic overview of the Bcl-2 family of proteins. (a) The Bcl-2 family of proteins is divided into three groups based on function and the presence of up to four Bcl-2 homology (BH) regions. The anti-apoptotic proteins and the multi-region pro-apoptotic proteins contain all four BH regions. The BH3 proteins contain only one conserved BH3 region. Most Bcl-2 family members contain a putative hydrophobic transmembrane (TM) region at the C-terminus that targets the proteins to intracellular membranes. *Bid is an example of an exceptional BH3 protein as it contains multiple BH regions. (b) The BH1-3 regions form a hydrophobic groove which serves as the interaction site for the BH3 region of other Bcl-2 family proteins. This figure is based on the crystal structure of Bcl-XL bound to the BH3 peptide of Bim (Liu, X., Dai, S., Zhu, Y., Marrack, P., Kappler, J.W., 2003. The structure of a Bcl-xL/Bim fragment complex: Implications for Bim function. *Immunity* 19, 341–352).

How Do Bcl-2 Family Proteins Regulate MOMP?

As the critical step in committing a cell to apoptosis, Bax and/or Bak oligomerize in the MOM forming a pore through which cytochrome c and other apoptogenic factors are released. Because both these proteins are present as monomers in cells, several models have been proposed to explain how their activation leads to oligomerization and how that is regulated by other Bcl-2 family members to ensure that MOMP only occurs in the appropriate cellular context (Figure 2(a)). According to the displacement model, Bax and Bak are constitutively active and therefore cell survival requires continuous inhibition of these proteins by binding to the anti-apoptotic proteins. During apoptosis, BH3 proteins displace activated Bax and Bak

from the anti-apoptotic proteins allowing them to oligomerize, enabling MOMP (Willis *et al.*, 2005, 2007; Chen *et al.*, 2005). In contrast, the direct activation model postulates that Bax and Bak are inactive and require activation to execute MOMP. As a consequence, BH3 proteins can be pro-apoptotic in two different ways, and can be classified as activators or sensitizers based on binding affinities for different sub-types of the multi-region Bcl-2 members (Figure 2(b)). Activator BH3 proteins bind to Bax and/or Bak directly to cause their activation, but also bind to anti-apoptotic proteins; this latter interaction does not necessarily lead to MOMP and is one mechanism by which anti-apoptotic proteins prevent apoptosis. By contrast BH3 sensitizers only bind to anti-apoptotic proteins. If the anti-apoptotic protein is already bound to an

Figure 2 Models of the mechanism of action for the regulation of MOMP by Bcl-2 family proteins. (a) In the displacement model, Bax and/or Bak are constitutively active and inhibited by the anti-apoptotic proteins. BH3 proteins compete for binding to the anti-apoptotic proteins displacing Bax and/or Bak thereby allowing them to oligomerize and permeabilize membranes. In the direct activation model, BH3 proteins are classified as activators or sensitizers. Activator BH3 proteins bind to and activate Bax/Bak. Anti-apoptotic proteins inhibit the activator BH3 proteins preventing MOMP. BH3 sensitizers bind to the anti-apoptotic proteins to displace the BH3 activators whereupon they bind to and activate Bax and/or Bak. The embedded together model includes both displacement and activation mechanisms and suggests that the interactions of Bcl-2 family proteins with membranes results in conformational changes that change the affinities of the proteins for each other. Thus implicit in this model is that all interactions including those with membranes are reversible and governed equilibria. At membranes, the anti-apoptotic proteins inhibit the activator proteins as well as Bax and Bak by sequestering them or preventing their binding to the membrane. Both activator and sensitizer proteins can recruit and sequester anti-apoptotic proteins in the membrane, a term defined as mutual sequestration. The unified model defines anti-apoptotic sequestration of activator proteins and Bax or Bak as mode 1 and mode 2, respectively. Inhibition by mode 1 is less effective than mode 2. Mode 2 also prevents mitochondrial fusion and promotes mitochondrial fragmentation. (b) Classification of BH3 proteins as activators or sensitizers and selectivity of binding between BH3 proteins and anti-apoptotic members. This figure is based on binding affinities obtained from Certo, M., Del Gaizo Moore, V., Nishino, M., *et al.*, 2006. Mitochondria primed by death signals determine cellular addiction to antiapoptotic BCL-2 family members. *Cancer Cell* 9, 351–365.

activator, the activator is displaced whereupon it can bind to and activate Bax and/or Bak. Thus, sensitizers cause MOMP indirectly, and only if the anti-apoptotic protein bound has a 'pre-bound' activator (Letai *et al.*, 2002; Kuwana *et al.*, 2005). Thus, these models differ significantly as to the functional state of Bax and Bak monomers and the mechanism by which anti-apoptotic proteins inhibit MOMP (Leber *et al.*, 2007).

Based on experiments that measured these binding interactions *in vitro*, the embedded together model proposed that the distinction between activator and sensitizer BH3 proteins was valid, but incomplete. This model suggested that anti-apoptotic family members inhibit MOMP by binding to and sequestering both the activators and activated Bax and/or Bak (Leber *et al.*, 2007; Lovell *et al.*, 2008; Billen *et al.*, 2008a). Furthermore it assigns the membrane a critical role in the

process, not only as a locus of interaction that is ultimately altered during MOMP, but also as a regulator of binding interactions as after interaction with membranes Bcl-2 family members undergo conformational changes that affect subsequent binding interactions. For example, Bid binds to and activates Bax only when both proteins are membrane bound. As a result, the entire process is governed by a series of reversible equilibria of protein–protein and protein–membrane interactions and the functional outcome depends on the relative protein concentrations and binding affinities. An additional feature of this model is that it assigns a dual role to BH3 proteins in that activators and sensitizers can also 'activate' their anti-apoptotic binding partners by promoting their insertion into the membrane. As binding of a membrane-bound anti-apoptotic protein to a BH3 protein or to Bax

and/or Bak inactivates both proteins, this mechanism is termed mutual sequestration (Leber *et al.*, 2010).

The unified model also recognizes that there are multiple mechanisms whereby anti-apoptotic proteins function by designating the sequestration of activators as MODE 1 and sequestration of activated Bax and/or Bak as MODE 2. In this model, inhibition of MODE 1 is less efficient and more easily de-repressed than MODE 2. As an important extension related to, but independent of apoptosis, inhibition by MODE 2 also prevents mitochondrial fusion and promotes mitochondrial fragmentation (Llambi *et al.*, 2011). Recently, the mechanism by which in healthy cells Bcl-XL transiently binds to peripherally membrane-bound Bax causing its relocation to the cytoplasm has been ascribed MODE 0 (Billen *et al.*, 2008a; Todt *et al.*, 2013; Edlich *et al.*, 2011; Westphal *et al.*, 2014).

Conformational Changes Associated with Bax and Bak Activation

In most cells Bax and Bak are described as functionally equivalent. However, evidence from animals (described below) suggests this may not be entirely correct. After binding to activator BH3 proteins both Bax and Bak undergo conformation changes permitting oligomerization that leads to the pore formation that is the structural basis for MOMP (Degenhardt *et al.*, 2002; Hsu and Youle, 1997; Griffiths *et al.*, 1999). Both Bax and Bak are composed of nine α helices: $\alpha 5$ and $\alpha 6$ are the two central hairpin helices, $\alpha 9$ contains the C-terminal TM region, and $\alpha 2-4$ forms the hydrophobic pocket (Suzuki *et al.*, 2000; Moldoveanu *et al.*, 2006). Despite these similarities in structure, conformational changes and function, there are still important differences between them.

In healthy cells, Bax is primarily cytosolic whereas Bak is inserted in the mitochondria and ER membrane. This difference in localization is attributed differences in the structure and configuration of the C-terminal TM region in $\alpha 9$ in the two proteins. After binding to BH3 activators, $\alpha 9$ of Bax is dislodged from the hydrophobic pocket allowing Bax to insert into membranes (Wolter *et al.*, 1997; Schinzel *et al.*, 2004; Annis *et al.*, 2005). In contrast, Bak bypasses this step since it is constitutively integrated in the membrane via its $\alpha 9$; this difference in spontaneous membrane insertion may be due to the increased hydrophobicity of the TM region of Bak compared to Bax (Ferrer *et al.*, 2012).

A common conformational change that occurs after activation of both Bax and Bak is the rearrangement of an amino terminal sequence that generates a neo-epitope (Hsu and Youle, 1997; Griffiths *et al.*, 1999). A transient interaction of Bax with membranes triggers this conformation change that is detected by the 6A7 antibody. This change is largely irreversible after binding to BH3 proteins and membranes (Yethon *et al.*, 2003). Structurally this neo-epitope emerges due to the unwinding of part of the Bax $\alpha 1$ helix after activation (Peyerl *et al.*, 2007). The specific change leading to epitope exposure after Bak activation has not been elucidated, but is proposed to be similar.

Another difference (albeit controversial) between Bax and Bak is the location and number of BH3 protein binding sites. The common interaction involves the BH3 region and the hydrophobic groove of BH1-3 that leads to conformational

change favoring the formation of oligomers. While the Bid BH3 peptide binds Bak at this canonical site, an alternative binding hydrophobic pocket termed the 'rear pocket' was identified as the interaction site for the Bim BH3 peptide on Bax (Gavathiotis *et al.*, 2008; Leshchiner *et al.*, 2013). Notably this pocket is located at the 'opposite side' of the protein compared to the canonical site (termed 'front pocket'). The $\alpha 1$ and 6 helices form the rear pocket and is masked by the $\alpha 1$, 2 loop in the unbound state. Binding of the Bim BH3 peptide results in a conformation change that facilitates the displacement of C-terminal $\alpha 9$ that mediates membrane binding, and also exposes the BH3 region (Kim *et al.*, 2009; Figure 3(a)). Displacement of $\alpha 9$ is followed by the insertion of $\alpha 5$, $\alpha 6$ and $\alpha 9$ onto or into the membrane (Czabotar *et al.*, 2013; Annis *et al.*, 2005).

Regardless of whether there are one or two activation binding sites on Bax, activation results in the exposure of the hydrophobic BH3 region required for Bax homodimerization (Dewson *et al.*, 2008; George *et al.*, 2007). However, the type of dimer that is formed will depend on which binding pocket this newly exposed BH3 region finds. There are two competing models to explain the propagation of Bax dimers into large pore forming oligomers. In the asymmetric dimer model, the exposed BH3 region of one Bax molecule activates another Bax molecule through binding to the rear pocket (Figure 3(b); Gavathiotis *et al.*, 2008). In contrast, the symmetric dimer model predicts that a Bax dimer forms when the BH3 region of one Bax molecule binds to the BH3 groove of another Bax molecule. Oligomer propagation occurs as a consequence of the interaction of two dimers via the rear pocket (Figure 3(c); Czabotar *et al.*, 2013; Brouwer *et al.*, 2014).

Physiology and Regulation of Bcl-2 Family Members

Although the role of Bcl-2 family members in regulating apoptosis was initially recognized in the context of over-expression secondary to a chromosomal translocation found in a human cancer, our understanding of the physiological functions of specific Bcl-2 family members has been greatly aided by genetic knockout mice studies. Mice with a genetic deletion of *BCL-2*, *BCL-XL* or *MCL-1* are not viable. *MCL-1* $-/-$ mice display a failure in embryonic implantation (Rinkenberger *et al.*, 2000). *BCL-XL* $-/-$ mice die during embryonic development and exhibit extensive neuronal and hematopoietic progenitor cell death (Motoyama *et al.*, 1995). *BCL-2* $-/-$ mice complete embryonic development but die postnatally displaying growth retardation, renal failure, extensive lymphocyte cell death and defects in hair pigmentation (Veis *et al.*, 1993). In contrast, Bcl-w knockout males are sterile and A1 knockout mice have accelerated neutrophil apoptosis (Hamasaki *et al.*, 1998; Print *et al.*, 1998).

Pro-apoptotic proteins are also important during development. While *BAK* $-/-$ mice are developmentally normal and *BAX* $-/-$ mice have limited abnormalities restricted to hyperplasia of lymphoid tissues and male sterility, mice lacking both *BAX* and *BAK* die perinatally from the accumulation of excessive cells in the hematopoietic and central nervous system. As expected, cells from these mice are resistant to various apoptotic stimuli (Knudson *et al.*, 1995; Lindsten *et al.*, 2000).

Figure 3 Models of Bax dimer formation. (a) Bax activation is triggered by interaction of a BH3 protein on the rear or front pocket. This interaction triggers the exposure of the BH3 region of Bax and insertion of the Bax into the membrane via the TM region. (b) Formation of asymmetric dimers: The exposed BH3 region of Bax and Bak interacts with the rear pocket of an adjacent Bax or Bak. Oligomer formation occurs by the subsequent interaction of the rear pocket and the BH3 regions. (c) Formation of symmetric dimers: The exposed BH3 regions of Bax and Bak interact with the hydrophobic groove of an adjacent Bax or Bak forming a homo-dimer. Pore formation occurs by subsequent oligomerization of homodimers presumably via interactions with the rear pocket.

In contrast, most mice lacking BH3 proteins are not affected developmentally, but display various tissue specific and signaling abnormalities (Table 1). As the BH3 domain is generally not required for the diverse non-apoptotic functions of BH3 proteins, it is likely that many of the defects observed in knockout animals are not due to alterations in apoptosis. Moreover, it is an open question for each family member as to which function evolved first. These proteins therefore serve as examples of intersecting nodes between cell death and metabolism, two processes that are tightly linked at many levels (Green *et al.*, 2014).

Since Bcl-2 family proteins are critical for maintaining the balance between life and death, their expression and activity is tightly controlled at multiple levels. At a transcriptional level, the expression of Bcl-2 family proteins is often increased in response to death or survival signals. For example, DNA damage results in the transcriptional activation by the tumor-suppressor P53 of pro-apoptotic NOXA, PUMA and BAX (Oda *et al.*, 2000; Nakano and Vousden, 2001; Miyashita *et al.*, 1994). By contrast, growth or survival signals cause the phosphorylation of STAT5 which acts as a transcriptional enhancer of BCL-XL (Silva *et al.*, 1999).

Function can also be regulated by alternative splicing: Bcl-XL and Bcl-XS are splice variants; the former anti-apoptotic

and the latter pro-apoptotic due to the absence of a critical domain (Grillot *et al.*, 1997; Boise *et al.*, 1993). Bim has three isoforms, of which BimS is constitutively active in cells because it lacks a dynein light chain binding domain that normally sequesters BimL and BimEL to the micro-tubule associated dynein motor complex (O'Connor *et al.*, 1998). The latter proteins are therefore held inactive but able to respond more rapidly than BimS that is regulated transcriptionally.

At the posttranslational level, many Bcl-2 proteins are regulated by posttranslational modifications including phosphorylation, myristoylation, ubiquitin-mediated degradation and proteolytic cleavage, most commonly in the unstructured loop region, BH3 region and in the TM (Kutuk and Letai, 2008). These posttranslational modifications directly affect protein localization, half-life (and therefore concentration), and binding affinity to other Bcl-2 family members. The modifications also affect binding to other regulatory proteins outside the Bcl-2 family. For example, in the presence of the IL-3 survival factor the pro-apoptotic Bad is phosphorylated, binds to 14-3-3 complexes and is thereby sequestered in the cytoplasm. Therefore the phosphorylation status of Bad can serve as a switch in function as de-phosphorylation of Bad results in dissociation from the 14-3-3 complex and binding to Bcl-XL at the membrane as a pro-apoptotic sensitizer

Table 1 Phenotypes of mice deficient in BH3 proteins

<i>BH3 protein deletion</i>	<i>Phenotypes in mice</i>	<i>References</i>
Bid	Mice are resistant to Fas mediated fatal hepatocyte apoptosis and hemorrhagic necrosis	Yin <i>et al.</i> (1999)
Bim	Mice have hyperplasia of lymphoid and myeloid cells and T cell development is perturbed. Lymphocytes are resistant to apoptosis induced by elevated Ca^{2+} by ionomycin, micro-tubule stabilization by taxol, and cytokine deprivation. With age, mice develop lymphadenopathy and a fatal systemic autoimmune disease	Bouillet <i>et al.</i> (1999)
Puma	Various cell types are resistant to apoptosis induced by DNA damage, cytokine deprivation and glucocorticoid exposure	Jeffers <i>et al.</i> (2003); Villunger <i>et al.</i> (2003)
Bad	Certain cell types display an increased resistance to epidermal or insulin-like growth factor mediated apoptosis. Lymphocytes have decreased IgG production. With age, mice develop B-cell lymphoma	Ranger <i>et al.</i> (2003)
Noxa	Mice exhibit increased resistance toward X-ray irradiation induced gastrointestinal death. Fibroblasts display mild resistance toward etoposide or γ irradiation	Villunger <i>et al.</i> (2003); Shibue <i>et al.</i> (2003)
Bmf	Mice have hyperplasia of B cells and mild hypergammaglobulinemia Thymocytes and pre-B cells are mildly resistant to apoptosis induced by glucocorticoids, and histone- deacetylase inhibition	Labi <i>et al.</i> (2008)
Bik	No obvious detectable defects	Coultas <i>et al.</i> (2005)
Beclin	Early embryonic lethality. Embryonic stem cells display abnormalities in autophagy induction	Yue <i>et al.</i> (2003)
Hrk	Some neuronal cell types displayed delayed apoptosis induced by nerve growth factor withdrawal	Coultas <i>et al.</i> (2007); Imaizumi <i>et al.</i> (2004)

(Zha *et al.*, 1996). Additionally in healthy cells, Bak is bound to mitochondrial outer membrane protein VDAC2, thereby preventing activation until it is displaced during death signal initiation by tBid, Bim or Bad (Cheng *et al.*, 2003).

Bcl-2 Proteins at the Endoplasmic Reticulum

While much research has focused on the regulation of MOMP by Bcl-2 family proteins, they have also been implicated in important processes at the ER such as modulation of calcium signaling (Oakes *et al.*, 2006; Rong and Distelhorst, 2008). During endoplasmic reticulum stress, Bax and Bak oligomerize at the endoplasmic reticulum causing the release of calcium into the cytosol (Scorrano *et al.*, 2003; Zong *et al.*, 2003; Nutt *et al.*, 2002). This can lead to both mitochondrial dependent and independent pathways of cells death although the latter is less well characterized (Heath-Engel *et al.*, 2008). As a potential mediator of this process, the BH3 protein Bik induces ER resident Bax and Bak to oligomerize and release calcium ultimately leading to MOMP and the release of cytochrome *c* (Mathai *et al.*, 2005). ER resident Bcl-2 affects calcium flux by directly or indirectly binding to the IP3 receptor calcium channel (Rong *et al.*, 2009). Additionally, Bcl-2 localized at the endoplasmic reticulum can inhibit apoptosis triggered by various stress signals (Zhu *et al.*, 1996; Bhatt *et al.*, 2008). Furthermore, Bcl-2 has been found to be present in a complex which includes the ER protein Bap31, another transmitter of apoptotic signals from the endoplasmic reticulum to mitochondria (Chami *et al.*, 2004; Rong *et al.*, 2009; Breckenridge *et al.*, 2003; Ng *et al.*, 1997).

The unfolded protein response (UPR) and autophagy are two additional complex cellular responses mediated at the ER that are also regulated by Bcl-2 family proteins. UPR occurs as a consequence of the accumulation of unfolded or misfolded

proteins in the lumen of the ER and triggers three signaling pathways mediated by ER localized ATF6, PERK and IRE-1, to restore normal function. Prolonged or excessive UPR results in apoptosis through PERK activation leading to CHOP-dependent transcriptional upregulation of *PUMA* and *BIM* (Puthalakath *et al.*, 2007; Ghosh *et al.*, 2012). A second arm of UPR mediation also requires the Bcl-2 family as Bax and Bak promote IRE-1 signaling (Hetz *et al.*, 2006).

Autophagy is a cell survival mechanism in which double membrane organelles called autophagosomes are induced to form around damaged cellular components such as misfolded proteins, protein aggregates and dysfunctional organelles. By regulated fusion with lysosomes the contents are catabolized and can be re-used to maintain cellular energy levels (Levine and Kroemer, 2008). Autophagy is therefore a survival mechanism, but autophagy can be driven to cell death through extensive degradation of critical organelles (Mukhopadhyay *et al.*, 2014). The initiation of autophagosome formation at the ER requires the BH3 protein Beclin-1 to co-ordinate a multi-protein complex (Axe *et al.*, 2008). Bcl-2 inhibits autophagy by directly binding to Beclin-1 in the presence of NAF-1 (Chang *et al.*, 2010; Rong *et al.*, 2008; Pattingre *et al.*, 2005). The BH3 protein Bad stimulates autophagy by displacing Beclin-1 from binding to Bcl-2 and Bcl-XL and allowing formation of the pre-autophagosome complex; thus there is direct cross talk between autophagy and apoptosis (Maiuri *et al.*, 2007).

Bcl-2 Family Proteins and Cancer

Cancers arise when cells acquire genetic or epigenetic abnormalities that cause uncontrolled proliferation. Apoptosis acts as a physiologic brake to this context-independent cell division (Meier *et al.*, 2000). Therefore the evasion of apoptosis is one of the required features for tumorigenesis and

many direct and indirect mediators of cell death are known to be abnormal in human and experimental cancer models, including Bcl-2 family proteins. In addition to the chromosomal translocations which led to the original discovery of *BCL-2*, many more common mechanisms have been observed including the amplification of the *BCL-2* gene as observed in small cell lung cancer and the loss of endogenous microRNAs that repress *BCL-2* gene expression as seen in chronic lymphocytic leukemia (Ikegaki *et al.*, 1994; Cimmino *et al.*, 2005). Amplification of *MCL-1* is one of the most common genetic abnormalities across cancers (Beroukhi *et al.*, 2010). Additionally, the inactivation of *BAX* by microsatellite insertions is common amongst many malignancies (Rampino *et al.*, 1997; Yamamoto *et al.*, 1997). Point mutations or posttranslational modifications altering the activity of BH3 proteins have also been reported, such as the somatic missense mutations reported in *BAD* in cases of colon adenocarcinoma. These mutations are predicted to reduce the binding affinity of Bad for Bcl-2 and Bcl-XL (Lee *et al.*, 2004).

Cancer and Addiction to Bcl-2 Family Proteins

Because of the requirement for preventing apoptosis to maintain continued proliferation of cancer cells, tumors are essentially 'addicted' to this inhibition. As critical regulators of MOMP, Bcl-2 family proteins are good (but not the only) candidates to achieve this (Certo *et al.*, 2006; Del Gaizo Moore *et al.*, 2007). Thus selective antagonism of anti-apoptotic Bcl-2 family proteins should be sufficient to kill those cancers where this represents the locus of addiction. The BH3 profiling assay is a powerful predictive tool to determine if regulation of MOMP by Bcl-2 family proteins is the locus, and to identify the nature of the addiction. To determine this, mitochondria are isolated from tumor cells and exposed to a panel of BH3 peptides representing the BH3 proteins. MOMP is measured by quantifying the release of cytochrome c from the mitochondria (Del Gaizo Moore and Letai, 2013). When MOMP is elicited, the pattern of release by effective and ineffective peptides can be divided into three classes with functional significance (Figure 4). The 'Class A' block occurs due to insufficient BH3 protein activation, and is overcome by adding activator BH3 peptides. 'Class B' block occurs due to a loss of the executors, Bax and Bak. Mitochondria with this block are insensitive to all BH3 peptides. In the 'Class C' block, MOMP is prevented by the overexpression of anti-apoptotic proteins which sequester the pro-activator molecules, and can be overcome by adding sensitizer BH3 peptides. Because of the specificity of BH3 sensitizers to different anti-apoptotic Bcl-2 family members, BH3 profiling can reveal which inhibitor(s) are present (Figure 2(b)). For example, Bad binds Bcl-2 and Bcl-XL (but not Mcl-1), whereas Noxa binds Mcl-1 and A1 (but not Bcl-2 or Bcl-XL). Thus mitochondria with a 'Class C' block are described as being 'primed' for death as an increase in the concentration of the relevant BH3 protein (or its mimetic as described in the next section) should elicit cell death in that tumor.

Bcl-2 Family Proteins as Therapeutic Targets

Targeting cell death with agents that affect Bcl-2 family proteins represents a new way to selectively target cancer cells that

contrasts with the broad toxicity of most standard anti-cancer drugs that are often selective only at concentrations that kill only dividing cells. As a result there is an emerging strategy to restore apoptosis in cancers is by antagonizing the activity of anti-apoptotic proteins using small molecules. Although several putative anti-apoptotic protein inhibitors have been identified, not all these agents have shown specificity for Bcl-2 family proteins as their mechanism of action (Vogler *et al.*, 2009).

The best characterized and furthest developed series of truly selective molecules have been designed by Abbot Laboratories and provide an instructive lesson in Bcl-2 family protein physiology. ABT 737 is a mimetic of the BH3 region of Bad and as such is a potent inhibitor of Bcl-2, Bcl-XL and Bcl-w; the closely related but better absorbed ABT-263 has been taken forward into clinical trials (Tse *et al.*, 2008). As a single agent, the results in hematological malignancies were encouraging. However, a dose limiting decrease in platelet counts (thrombocytopenia) was observed that represents an 'on-target' effect, as inhibition of Bcl-XL is known to predictably decrease platelet life-span (Vogler *et al.*, 2011). As this effect is limited to Bcl-XL among the anti-apoptotic proteins, a new compound, ABT-199 was designed which binds to Bcl-2 but not to Bcl-XL or Bcl-w (Souers *et al.*, 2013). While ABT-199 works extremely efficiently for some hematological malignancies, presumably there will be some tumors that are resistant because they are addicted to Bcl-XL rather than Bcl-2. Furthermore, solid tumors are also more resistant, and this phenomenon may be attributed to resistance conferred by Mcl-1 which is not affected by ABT-199 (or ABT-263), and thus represents another important target (van Delft *et al.*, 2006; Varin *et al.*, 2010). An important unanswered question for all approaches that inhibit anti-apoptotic Bcl-2 family proteins is whether specificity for cytotoxicity against cancer cells will be retained when these agents are combined with other cancer therapies.

While restoring apoptosis in addicted cancers by antagonizing the activity of the anti-apoptotic proteins using small molecules is promising and in clinical development, the pharmacologic modulation of pro-apoptotic Bax and Bak activity is another promising approach that is being explored. The small molecules BAM7, SMBA1 and compound 106, have been identified as potential candidates with differing putative mechanisms of action. While BAM7 activates Bax by binding the rear pocket similar to the Bim peptide, compound 106 is predicted to bind to the front pocket (Gavathiotis *et al.*, 2012; Zhao *et al.*, 2014). In contrast, SMBA1 is proposed to block the phosphorylation of Bax at serine 184. This phosphorylation is a negative regulator of Bax function, and preventing it should de-repress Bax (Xin *et al.*, 2014).

Summary

The Bcl-2 family proteins are critical regulators of cell death at the mitochondria and the ER. Bcl-2 family proteins regulate this process by a series of protein-protein and protein-membrane interactions that are associated with complex conformational changes in the proteins that ultimately control

Figure 4 BH3 profiling to identify blocks in apoptosis. In BH3 profiling, mitochondria are incubated with BH3 peptides as representatives of their cognate proteins to examine the pattern of apoptosis response as measured by MOMP *in vitro*. In the ‘Class A’ block, Bax and Bak are inactive and functional BH3 proteins are low or missing and hence MOMP occurs only in response to added activators but not sensitizers. In the ‘Class B’ block, Bax and/or Bak are absent or nonfunctional. Thus, the mitochondria do not respond to the addition of any BH3 peptide. In the ‘Class C’ block, mitochondria are sequestering activator BH3 proteins or activated Bax or Bak. In this scenario, sensitizer peptides induce MOMP based on their specific binding affinities to different anti-apoptotic members. These cancers are said to be ‘primed’ and are candidates for therapies based on inhibitors the anti-apoptotic proteins.

the formation of pores in organelle membranes. Although most, if not all, of the players have been identified, rigorous quantitative modeling of these interactions is still in its infancy and promises great insights in the future (Gaudet *et al.*, 2012). From a therapeutic point of view the concept that ‘addiction’ to anti-apoptotic Bcl-2 members is relevant for cancer maintenance has led to the development of small molecule Bcl-2 inhibitors designed based on structural and functional insights derived from two decades of research. From this perspective, it will be exciting to investigate small molecules that target other interactions among Bcl-2 family members, and to see how such agents fit into treatment as monotherapy or combined with other drugs.

Inhibitor of Apoptosis Proteins, the Sentinels of Cell Death and Signaling

M Cristina de Almagro and D Vucic, Genentech, South San Francisco, CA, USA

Glossary

Apoptosis It is a programmed type of cell death that requires caspases activation. Apoptosis is characterized by cellular shrinkage, nuclear fragmentation, chromosome condensation, blebbing of the plasma membrane, and late loss of plasma membrane integrity.

Necroptosis It is a regulated form of cell death that does not involve caspase activation but requires kinases RIP1 and

RIP3. This type of cell death is characterized by organelle swelling, lack of nuclear fragmentation, early loss of plasma membrane integrity and inflammation.

Ubiquitination It is a posttranslational modification where ubiquitin is attached to a lysine or N-terminal methionine on a substrate protein. Ubiquitination is carried out by three enzymes: E1, E2, and E3 with E3 ubiquitin ligases providing substrate specificity.

Proper regulation of cell death and survival is crucial for cellular and organismal homeostasis. To this end, eukaryotes have evolved numerous proteins to achieve a fine-tuned and precise control of cell fate. Importantly, dysregulated cell death can lead to severe diseases such as cancer or neurodegeneration. Inhibitors of Apoptosis, or IAP, proteins constitute a family of 8 proteins that are critically involved in inhibition of cell death, but also in proinflammatory signaling, cell division and migration (Salvesen and Duckett, 2002; Fulda, 2007). Interestingly, even though all the IAP family members are involved in the regulation of cell survival, they do it in quite different ways.

Structural Organization of IAPs

IAP proteins and their signature Baculovirus IAP repeat (BIR) domains were first identified in baculoviruses. Infection of insect cells with baculoviruses triggers cell death that can be inhibited by virally encoded antiapoptotic proteins (Birnbaum *et al.*, 1994; Clem *et al.*, 1991). Genetic screens based on rescuing cell death caused by infection with baculovirus strains deficient for caspase inhibitor p35 lead to the identification of baculovirus inhibitors of apoptosis as the mediators of cell death resistance (Birnbaum *et al.*, 1994; Clem *et al.*, 1991; Crook *et al.*, 1993).

BIR Domain

The evolutionarily conserved IAP family is characterized by the presence of at least one BIR domain (Figure 1). Some members of the IAP family have three BIR domains such as c-IAP1, c-IAP2, XIAP, and NAIP, while others have one: ML-IAP, Survivin, ILP-2, and Bruce. Apart from the BIR domain, IAP proteins have a diversity of other domains that confer the specific functions and characteristics of each member of the IAP family (Varfolomeev and Vucic, 2011).

The BIR domain is approximately 70–80 amino acids, and contains a zinc-binding site (Birnbaum *et al.*, 1994). Functionally, the BIR domains allow protein–protein interactions, and for XIAP, they mediate interactions with caspases (Srinivasula and Ashwell, 2008; Vaux and Silke, 2005). Many

of the BIR-mediated protein–protein interactions occur through a pocket on the BIR domains that binds to an N-terminal tetrapeptide motif called IAP-binding motifs (IBMs). But, the specific BIR sequence of each IAP protein is very important since small variations in the sequence can lead to different interaction partners:

- XIAP: binds caspase-3 and -7 via BIR2 and the preceding linker region; and SMAC/Diablo (Secondary mitochondria-derived activator of caspases) and caspase-9 through BIR3
- c-IAP1/2: bind TRAF2 via BIR1 and SMAC through BIR3
- ML-IAP, ILP-2, and Bruce: bind SMAC.

RING, UBC, and UBA Domains

The IAP proteins c-IAP1, c-IAP2, XIAP, and ML-IAP contain a really interesting new gene (RING) domain that confers E3 ligase ubiquitin activity. The RING domain allows these IAPs to regulate their binding partners by ubiquitination, as well as to promote their autoubiquitination. Ubiquitination is a three-step process initiated by an E1 ubiquitin-activating enzyme followed by charging an ubiquitin-conjugating E2 enzyme and finalized an E3 ligase that allows the transfer of the ubiquitin moiety to a lysine on the substrate protein forming monoubiquitins or ubiquitin chains (Hershko and Ciechanover, 1998; Pickart and Fushman, 2004). When ubiquitin chains are assembled, different linkages between ubiquitins can be formed depending on the ubiquitin lysine used or the N-terminal methionine. There are eight different kinds of ubiquitin chains: linear (through N-terminus), K6, K11, K27, K29, K33, K48, K63. K48 chains usually target proteins for proteasomal degradation, while K11 and K63 polyubiquitin chains trigger the formation of signaling complexes. The RING domains of IAP proteins mostly collaborate with UbcH5 and UbcH6 E2 enzymes to promote ubiquitination (Dynek *et al.*, 2010; Varfolomeev *et al.*, 2012a,b).

Instead of a RING domain, Bruce has a ubiquitin-conjugating (UBC) domain that allows the transfer of ubiquitin moieties to its substrates (Hauser *et al.*, 1998). XIAP, c-IAP-1/2, and ILP-2 also contain a ubiquitin-associated (UBA) domain that allows the binding to various ubiquitin moieties (Dynek

Figure 1 Inhibitor of apoptosis protein family members. The structural organization of the eight IAP protein.

et al., 2010; Blankenship *et al.*, 2009; Gyrd-Hansen *et al.*, 2008).

CARD, NATCH, and LRR Domains

The caspase activating and recruitment domain (CARD) present in c-IAP1 and 2 does not have a clear function yet (Hofmann *et al.*, 1997). Usually the CARD domain allows the interaction with other CARD-containing proteins, but c-IAP CARD binding partners have proven elusive thus far.

The only IAP protein with a NATCH domain is NAIP. The NATCH domain is found in proteins involved in immunity and NOD (nuclear binding and oligomerization domain)-mediated signaling pathways that sense intracellular pathogens. It consists of a NTPase domain and its name arises from the first letters of the proteins NAIP, CIITA, HET-E, and TP1 (Koonin and Aravind, 2000). NAIP also possesses a leucine-rich repeat (LRR) domain that gives it the ability to sense intracellular pathogens.

IAP Protein Characteristics and Function

XIAP (BIRC4)

Apoptosis regulated by XIAP

X-linked Inhibitor of apoptosis protein was found through sequence homology with baculovirus IAPs (Duckett *et al.*, 1996). XIAP primarily blocks apoptosis by directly inhibiting several caspases. XIAP can regulate either extrinsic apoptosis (induced by death ligands) or intrinsic apoptosis (mitochondria dependent intracellular signals) (Figure 2). The BIR3 domain of XIAP binds and inhibits caspase-9 by blocking its dimerization, which is needed for autocleavage. BIR2 and the linker region between BIR1 and BIR2 are responsible for the binding and inhibition of the active caspases-3 and -7 (Chai *et al.*, 2001; Riedl *et al.*, 2001; Eckelman *et al.*, 2006; Scott *et al.*, 2005). The E3 ligase activity of XIAP may also contribute to

the inhibition of apoptosis by targeting SMAC, caspases and other pro-apoptotic proteins for proteasomal degradation (Vucic *et al.*, 2011).

IAP proteins and NOD2 signaling

The NOD1/2 pathway is involved in innate immunity as NOD proteins sense pathogens and regulate the expression of genes involved in pathogen-host defense. NOD1/2 are intracellular sensors that oligomerize upon binding to their ligands, and recruit the kinase RIP2 (receptor TNFRSF-interacting serine-threonine kinase 2), XIAP and c-IAPs (Bertrand *et al.*, 2009; Krieg *et al.*, 2009; Damgaard *et al.*, 2012). The binding of these E3 ligases triggers the ubiquitination of RIP2 allowing the recruitment of TAK1, TAB1/2/3, Nemo (NF-kappa-B essential modulator) and LUBAC (linear ubiquitin chain assembly complex) leading to the NF- κ B, MAP kinases p38 and c-Jun N-terminal kinases (JNK) activation (Hasegawa *et al.*, 2008).

Mutations in XIAP were recently found in patients with the X-linked lymphoproliferative syndrome type-2 (XLP2). These mutations were found in the BIR2 and RING domains of XIAP, and resulted in impaired NOD1/2 (nucleotide-binding oligomerization domain) signaling. XLP2-related mutations found in XIAP prevent the binding of XIAP to RIP2 and subsequent ubiquitination of RIP2 by XIAP. Without ubiquitination of RIP2, NF- κ B, and MAPK signaling pathways cannot get activated thus preventing the expression of genes important for innate immunity and pathogen defense (Damgaard *et al.*, 2013).

c-IAP1 (BIRC2) and c-IAP2 (BIRC3)

Cellular inhibitors of apoptosis proteins are probably the best-studied members of the IAP family. These two proteins share the same domain structure and a noticeable sequence homology. Not surprisingly, their activities are highly redundant (Varfolomeev and Vucic, 2008). One explanation for the existence of these two proteins, which arose likely from gene

Figure 2 The intrinsic and extrinsic apoptotic pathways. IAPs can inhibit apoptosis triggered by external or intracellular stimuli.

duplication, is the critical nature of the cellular processes that they regulate. However, in some specific cell lineages such as B cells and T cells, differential roles between c-IAP proteins have been observed (Conze *et al.*, 2010; Giardino Torchia *et al.*, 2013).

It was initially thought that c-IAPs could bind to caspases and inhibit them, but it is clear now that although they interact with some caspases, they have very little inhibitory activity (Eckelman and Salvesen, 2006). The main mechanism by which c-IAPs inhibit apoptosis is likely the regulation of caspase-8 activation through RIP1 ubiquitination, as well as by the modulation of NF- κ B signaling pathways. NF- κ B signaling induces the transcription of pro-survival and cell growth genes via two different pathways: canonical and noncanonical.

IAP proteins and NF- κ B pathways

When the cytokine TNF α (Tumor Necrosis Factor α) binds to the death receptor TNFRI (TNF receptor I) in the plasma membrane, it induces the trimerization of TNFRI that triggers the assembly of TNFRI signaling complex (Figure 3). First to bind the intracellular domain of TNFRI is the adaptor protein TRADD (TNF receptor-associated death domain protein), followed by the protein kinase RIP1 and TRAF2 (tumor necrosis factor receptor-associated factor 2). TRAF2 also trimerizes, and it behaves as the adaptor protein that brings c-IAP1 and c-IAP2 to the TNFRI complex. c-IAPs are the only members of the IAP family capable of binding TRAF1 and TRAF2 through the first two α helices in their BIR1 domains (Samuel *et al.*, 2006; Varfolomeev *et al.*, 2006). Proximity within TNFRI complex permits c-IAP proteins dimerization, leading to the activation

of their E3 ubiquitin ligase activity. c-IAPs ubiquitinate RIP1 with K11- and K63-linked polyubiquitin chains, which allows the recruitment of downstream mediators of the NF- κ B signaling pathway to the TNFRI complex (Varfolomeev *et al.*, 2008). The essential role of c-IAPs in preventing apoptosis is mainly mediated by ubiquitination as these ubiquitination events prevent the translocation of RIP1 to the caspase-8-containing complex and cell death induction. Besides the key inhibition of Complex II formation (Caspase-8-containing complex), RIP1 ubiquitination also contributes to cell survival by NF- κ B activation. c-IAPs can ubiquitinate other molecules of the NF- κ B pathway as well, such as NEMO and TRAF2, and that ubiquitination modulates the activity of signaling complexes (Vucic *et al.*, 2011). Upon RIP1 and NEMO ubiquitination by c-IAPs, the IKK, TAB2/3-TAK1 and the LUBAC (HOIP, HOIL and Sharpin) complexes bind to ubiquitinated RIP1 and NEMO (Shim *et al.*, 2005; Wang *et al.*, 2001) leading to their activation, which results in the phosphorylation of I κ B α (inhibitor of kappa B) by the kinase IKK β . I κ B α sequesters NF- κ B transcription factors in the cytoplasm, but once it gets phosphorylated it undergoes ubiquitination and proteasomal degradation. This frees the NF- κ B transcription factors p50 and RelA/p65 to move into the nucleus and induce the transcription of cell survival genes (Scheidereit, 2006). In a positive feedback loop, c-IAP2 expression is upregulated by NF- κ B activation (Wang *et al.*, 1998).

Noncanonical NF- κ B pathway uses a different mechanism to activate the translocation of the NF- κ B transcription factors to the nucleus. Noncanonical NF- κ B signaling is slower than canonical NF- κ B: while the canonical pathway takes minutes

Figure 3 Canonical and noncanonical NF- κ B pathways. c-IAPs regulate the two different activation routes of NF- κ B signaling pathway.

for activation, noncanonical signaling takes hours to get activated (Dejardin, 2006). Interestingly, c-IAPs have opposite roles in the activation of these pathways: in canonical NF- κ B signaling c-IAPs are needed for the pathway activation, whereas noncanonical signaling requires loss of c-IAP proteins (Varfolomeev and Vucic, 2008).

Several TNF family ligands (TWEAK, LIGHT) can induce noncanonical NF- κ B signaling upon binding to their respective receptors. Cellular IAPs are recruited to these receptor complexes through the adaptor protein TRAF2 (Varfolomeev *et al.*, 2012a,b). The E3 ligase activity of c-IAPs constitutively ubiquitinates NIK (NF- κ B Inducing Kinase) to target it for proteasomal degradation and keep the NF- κ B signaling switched off (Vallabhapurapu *et al.*, 2008). When c-IAPs are not present, newly synthesized NIK accumulates in a period of a couple of hours. Once NIK protein reaches a certain threshold level, it phosphorylates IKK α /IKK β , leading to p100 phosphorylation and partial proteasomal processing to yield the p52 form (Dejardin, 2006). Transcription factor p52 then translocates to the nucleus in complex with RelB leading to the transcription of NF- κ B dependent genes.

Cell death ligand driven apoptosis and necroptosis

Cellular IAP proteins regulate two different types of cell death: apoptosis and necroptosis (Silke and Meier, 2013). Apoptosis is a caspase-dependent programmed type of cell death, while necroptosis is also a regulated form of cell death, but caspase

independent. In addition to being caspase-independent, necroptosis can be differentiated from apoptosis because it undergoes with organelle swelling, no nuclear fragmentation, early loss of plasma membrane integrity, inflammation, and requires the expression of the protein kinase RIP3, while apoptosis does not present these features (Zong and Thompson, 2006).

The mechanism by which c-IAPs regulate extrinsic apoptosis and necroptosis is essentially the same, as both pathways share the first signaling steps. When TNF α binds and activates the TNFR1, and c-IAPs are not present to ubiquitinate RIP1, RIP1 leaves the TNFR1-associated complex, or Complex I, and binds the FAS-associated protein with death domain (FADD)-caspase-8/10 complex (Feoktistova *et al.*, 2011; Figure 2). Once this Complex II is formed, cells may undergo apoptosis or necroptosis based on the activation of caspases and the presence of the kinase RIP3. After c-IAP depletion, cells could die of apoptosis if caspase-8/10 gets activated to start the caspase signaling cascade that will lead to apoptotic cell death. However, when caspases are not active or are inhibited cells find an alternative way to die: necroptosis. In this case, the kinase RIP3 will bind to the kinase RIP1 and they will get phosphorylated, leading to the phosphorylation of the pseudokinase MLKL (Mixed lineage kinase like) (Sun *et al.*, 2012; Zhao *et al.*, 2012; Figure 4). RIP3-mediated phosphorylation of MLKL causes MLKL oligomerization and translocation to the plasma membrane to mediate cell death (Cai *et al.*, 2014).

Figure 4 Necroptosis. RIP1, RIP3, and MLKL are crucial proteins for the necroptotic pathway. Their activation is based on auto- and cross-phosphorylation.

Therefore, c-IAPs are not just inhibitors of apoptosis proteins; they can also inhibit necroptotic cell death.

c-IAPs in immunity

Apart from the functions of c-IAPs in cell death, many groups have been trying to elucidate the importance of cellular IAP proteins in innate immunity and inflammation (Silke and Brink, 2010). In addition to their seminal roles in NF- κ B activation and the transcription of cytokines and inflammatory consequences of cell death, c-IAPs have been found to be involved in pathogen sensor pathways mediated by Toll-like receptor (TLR) 4 and retinoic acid-inducible gene I (RIG-I) (Vandenabeele and Bertrand, 2012).

TLR4 is a membrane bound protein that senses the bacterial lipopolysaccharide (LPS). Once it gets activated, TLR4 forms a complex with myeloid differentiation primary response 88 (MyD88) and TIR-domain-containing adapter-inducing interferon- β (TRIF), and recruits TRAF3 and TRAF6. c-IAPs regulate this pathway by ubiquitinating TRAF3 and targeting it for proteasomal degradation (Tseng *et al.*, 2010). This allows MyD88 to leave the membrane and go to the cytosol to activate the MAPK pathway that would lead to cytokine expression.

RIG-I is an intracellular sensor of dsRNA that is involved in viral defense (Yoneyama *et al.*, 2004). c-IAPs can be recruited to the RIG-I complex together with TRAF3, and ubiquitination of TRAF3 by c-IAPs participates in the activation of the interferon I response (Mao *et al.*, 2010).

ML-IAP (Livin or BIRC7)

Melanoma-IAP, with its single BIR domain can bind SMAC and with its RING domain it can promote SMAC ubiquitination and proteasomal degradation (Vucic *et al.*, 2005). ML-IAP is a very weak inhibitor of caspases but it binds SMAC with high affinity. Thus, it has been postulated that its role in apoptosis is not due to the direct inhibition of caspases, but to its competition with XIAP for the binding of SMAC (Vucic *et al.*, 2005, 2002). By acting as a SMAC sink, ML-IAP can free XIAP from SMAC inhibition and facilitate the inhibition of caspases (Figure 2). Apart from its role in inhibiting apoptosis through caspases and SMAC, ML-IAP (similarly to XIAP and c-IAP1) has been implicated in the migration of melanoma cells by binding to c-RAF and activation of the signaling pathway of MAPK (Oberoi-Khanuja *et al.*, 2012). Also, ML-IAP has a role

in cell proliferation inhibition, since its absence can induce cell cycle arrest (Wang *et al.*, 2007).

As its name indicates, ML-IAP is overexpressed in melanomas, but also in other tumors (Vucic *et al.*, 2000). Microphthalmia-Associated Transcription Factor (MITF), a protein responsible for the lineage differentiation of melanocytes, regulates ML-IAP expression in melanomas (Dynek *et al.*, 2008). Interestingly, physiological expression of ML-IAP seems to be predominantly in the eyes, although the functional relevance of eye expression has not been fully understood yet (Varfolomeev *et al.*, 2012a,b).

NAIP (BIRC1)

Neuronal apoptosis inhibitory protein was the first human IAP discovered and it was suspected that NAIP was responsible for the severe form of spinal muscular atrophy (SMA) (Roy *et al.*, 1995). Later, it was determined that the neighboring gene, survival motor neuron (SMN), was the culprit (Campbell *et al.*, 1997; Sertic *et al.*, 1997). Nevertheless, NAIP was shown to block cell death induced by a variety of stimuli (Liston *et al.*, 1996).

The presence of the NBD and LRR domains makes NAIP not only a member of the IAP family, but also of the NLR (nucleotide-binding domain [NBD]- and leucine-rich repeat [LRR]-containing) family of proteins. These proteins are involved in the immune response as intracellular sensors of pathogens.

In mice, NAIP is represented by different paralogs that are responsible for detecting pathogen components such as flagellin, a component of the flagella of bacteria (Tenthorey *et al.*, 2014; Kofoed and Vance, 2011). After the detection of the pathogen, several NAIPs can bind the NLR family CARD-containing 4 (NLRC4) protein and oligomerize it. NLRC4 then uses its CARD domain to activate caspase-1 (von Moltke *et al.*, 2013). Caspase-1 cleaves and activates the inflammatory cytokines IL-1 β and IL-18, and initiates pyroptotic cell death (von Moltke *et al.*, 2012). This form of cell death is one of the main mechanism by which infected cells are cleared (Lightfield *et al.*, 2008). It is still not clear how this pathway operates in humans, but so far it has been observed that overexpression of NAIP makes cells less permissive to pathogen growth (Vinzing *et al.*, 2008).

Survivin (BIRC5)

Survivin is the smallest of the IAP family members with a strong expression pattern in human cancers. Survivin is mainly expressed in tumors and not in normal tissue (with the exception of embryonic development, stem cells, thymus, testes, regenerating hepatocytes, and endothelial cells) representing a very promising target for drug development (Fukuda and Pelus, 2006; Chiou *et al.*, 2003). The expression of survivin correlates with tumor resistance to chemotherapy and radiotherapy, so drugs targeting survivin could have a great impact in cancer treatment.

Survivin has been implicated in numerous cellular pathways: mitosis, apoptosis, autophagy, DNA damage, and its cellular localization plays an important role for its many

functions (Wang *et al.*, 2011; Altieri, 2003). However, the physiological role of Survivin is in regulation of cell cycle. Survivin binds microtubules to contribute to the chromatin-associated spindle formation, and together with other proteins it forms the chromosomal passenger complex (CPC) (Altieri, 2008). Furthermore, the levels of survivin change during the cell cycle: they peak in M-phase but are very low in cells under G1-arrest (Li *et al.*, 1998).

Survivin has different splicing variants; from one mRNA five proteins are produced: survivin, survivin-2 α , survivin-2B (with duplicated 2nd exon), survivin- Δ -Ex-3 (with missing 3rd exon), and survivin-3B. These proteins have similar and distinctive functions, for example survivin-2B is an apoptotic inhibitor, while survivin- Δ -Ex-3 is not (Mahotka *et al.*, 2002). Survivin forms homodimers, so some of these splice variants could compete with survivin to form heterodimers with different functions.

Apollon or Bruce (BIRC6)

Bruce (BIR repeat containing ubiquitin-conjugating enzyme) is the biggest and the only member of the IAP family that is found on the membranes (Hauser *et al.*, 1998). Apart from the BIR domain, Bruce contains a UBC domain that allows ubiquitin conjugation. The E2 activity is very important for Bruce-mediated inhibition of apoptosis. Besides its auto-ubiquitination and proteosomal degradation, Bruce can promote ubiquitination of important apoptotic proteins such as SMAC/Diablo, caspase-9 and HtrA2 (Bartke *et al.*, 2004; Hao *et al.*, 2004; Sekine *et al.*, 2005).

Bruce is critical for cell survival, at least in embryonic development, since knockout mice die during embryogenesis or early after the birth. But the mechanism of action by which Bruce regulates cell death is not clear. Some studies show that Bruce knockout embryos do not have extensive apoptosis (Lotz *et al.*, 2004). Nevertheless, other studies indicate that the absence of Bruce induces apoptosis in the placenta because it stabilizes p53, which translocates to the nucleus and modulates the expression of genes involved in cell death leading to the activation of caspases (Lopergolo *et al.*, 2009; Ren *et al.*, 2005).

The importance of Bruce as an antiapoptotic protein is also supported by its role in cell cycle. In order to enter into mitosis, the proteins Cyclin A and B need to be degraded, mostly due to the E3 ligase APC/C (anaphase-promoting complex/cyclosome). However, Bruce also contributes to the ubiquitination and degradation of Cyclin A, allowing the cell to continue through the cell cycle and undergo mitosis (Kikuchi *et al.*, 2014).

Unlike other IAPs, the role of Bruce in cancer is not clear – it has been found overexpressed in some cancers, and it may confer resistance to some DNA damage chemotherapeutics, but more studies are needed to resolve this question (Sung *et al.*, 2007).

ILP-2 (BIRC8)

The expression of inhibitor of apoptosis protein-like 2 is limited to testis and lymphoblastoid cells. The amino acid sequence of ILP-2 is very similar to the C-terminal region of XIAP, making it likely that ILP-2 originated through a partial

duplication of XIAP (Lagace *et al.*, 2001; Richter *et al.*, 2001). ILP-2 can bind and inhibit caspase-9 but very weakly, probably because ILP-2 is a very unstable protein (Shin *et al.*, 2005). In addition, ILP-2 is not capable of blocking cell death triggered by Fas or TNF α .

Targeting IAP Proteins

IAP proteins are important modulators of cell death and thus, they are attractive therapeutic targets for diseases with dysregulated cell death such as cancer (Fulda and Vucic, 2012).

IAP Antagonists

The crucial role of c-IAPs and XIAP in inhibiting apoptosis has led to the idea that their antagonism could have a therapeutic benefit. These IAP proteins are often overexpressed in cancers, so their inhibition could be used to trigger apoptosis in tumors (Tamm *et al.*, 2000).

SMAC mimetics – IAP antagonists are small molecules that have been developed to mimic the way endogenous SMAC/Diablo binds IAP proteins. SMAC, as a dimer, is an endogenous IAP antagonist that is released from the mitochondria intermembrane space into the cytosol after apoptotic stimuli. The N-terminal tetrapeptide AVPI (Ala-Val-Pro-Ile) is responsible for binding the peptide-binding groove called IBM on the surface of select BIR domains of IAP proteins (Wu *et al.*, 2000). SMAC binds with high affinity to the BIR3 of XIAP, c-IAP1 and c-IAP2, the single BIR domain of ML-IAP, and it can bind the BIR2 of XIAP and the other IAPs with a lower affinity (Wu *et al.*, 2000). The binding of IAP antagonists to the select BIR domains of XIAP and c-IAP proteins can lead to cell death, but through different mechanisms.

In basal conditions, c-IAPs are folded in a way that occludes the RING domain. Binding of IAP antagonists to c-IAPs causes a conformational change that triggers the opening of c-IAP1 structure and exposes the RING domain (Dueber *et al.*, 2011). In this open conformation, the RING domain is free to dimerize with another RING domain. When this occurs, the E3 ubiquitin ligase activity is activated and c-IAPs get autoubiquitinated very rapidly, targeting themselves for proteasomal degradation (Dueber *et al.*, 2011; Feltham *et al.*, 2011). When c-IAPs are no longer present, RIP1, a crucial mediator of the pro-survival NF- κ B signaling pathway, cannot get ubiquitinated to recruit LUBAC, NEMO, TAK and TAB (Varfolomeev *et al.*, 2008; Bertrand *et al.*, 2008). Non-ubiquitinated RIP1 leaves the TNFRI-associated signaling complex and binds to caspases-8/10 and FADD forming the complex II (Bertrand *et al.*, 2008; Varfolomeev *et al.*, 2007; Vince *et al.*, 2007). Once complex II is formed, caspases-8/10 get activated and processed initiating the caspases cascade that leads to apoptotic cell death.

XIAP mechanistically inhibits apoptosis differently from c-IAPs, as XIAP directly inhibits several caspases. The binding of IAP antagonists to XIAP blocks the binding site to caspases, thus preventing caspase inhibition and resulting in cell death (Gao *et al.*, 2007; Varfolomeev *et al.*, 2009). Some IAP antagonist can promote slow XIAP ubiquitination and degradation, but that is probably not the main mechanism of action of IAP antagonists in XIAP neutralization.

One of the problems facing the therapeutic development of IAP antagonists is the relative insensitivity of numerous cancer cells to their action. IAP antagonists rely on the synthesis and secretion of TNF α to activate TNFRI, which, in the absence of c-IAPs, leads to the migration of RIP1 to caspase-8 complex. IAP antagonists usually stimulate TNF α production by activating NF- κ B signaling pathways (Petersen *et al.*, 2007). However, some cells do not activate NF- κ B signaling sufficiently to upregulate TNF α and activate TNFRI, thus not allowing IAP antagonists as single agents to induce cell death in many cancer cell types. Nevertheless, combination of IAP antagonists with TNF α , produced by neighboring cells or tissues can overcome this hurdle. Currently, IAP antagonists are tested in clinical trials to investigate their therapeutic benefit in human cancers (Fulda and Vucic, 2012; Flygare and Fairbrother, 2010).

Survivin Antisense Oligonucleotides

Survivin is an attractive therapeutic target since it is expressed mainly in cancer cells and not in normal tissues. One of the approaches that has been explored for targeting survivin utilizes gene therapy. An antisense oligonucleotide, LY2181308, is presently examined in cancer clinical trials with no critical toxicity observed so far (Tanioka *et al.*, 2011; Erba *et al.*, 2013). LY2181308 is a second-generation 2'-O-methoxyethyl, phosphorothioate antisense oligonucleotide. This antisense oligonucleotide binds to Survivin mRNA and suppresses protein translation, thus causing cell death.

Concluding Remarks

The careful regulation of cell death and survival is essential for proper maintenance of organismal homeostasis, and deregulated cell death can lead to neurological defects, infections and cancer. IAP proteins are evolutionarily conserved pro-survival mediators that regulate cell death and various signaling pathways (e.g., NF- κ B and NOD) to control cellular fate. Potent anti-cell death activity, elevated expression in many cancer types, and contribution to survival signaling pathways make IAP proteins promising targets for therapeutic intervention in human malignancies. However, our understanding of IAP proteins and cellular processes they regulate is far from complete and future studies, both in basic research and in clinical setting, should focus on fully unraveling the biological roles of IAP proteins and thereby open up additional therapeutic strategies.

Mitotic Catastrophe

RYC Poon, Hong Kong University of Science and Technology, Clear Water Bay, Hong Kong

Introduction

Proper control of cell number is dictated by a delicate balance between cell division and cell death. Dysregulation of this equilibrium underlies many human disorders including cancer. Progress in the past decade has unraveled some of the underlying principles of a specific form of cell death termed mitotic catastrophe. Although its biological significance and mechanism remain to be fully defined, the prevailing view is that mitotic catastrophe plays an essential role in preventing genome instability.

Mitosis is associated with profound changes in the cell's morphology and biochemistry. Although occupying just a fraction of the time of the whole cell cycle, mitosis is a period particularly prone to irreversible errors. Elaborated mechanisms have developed to ensure that chromosomes are segregated timely and accurately. Defects of these checks and balances are believed to be the major driving forces of aneuploidy. Accordingly, the role of mitotic catastrophe in eliminating cells that are unable to execute mitosis properly is crucial for maintaining genome stability.

Another salient aspect of mitotic catastrophe is that many current and emerging anticancer therapies are based on targeting mitosis. These range from classic spindle poisons to inhibitors that target mitotic regulators such as Eg5, Aurora kinases, and polo-like kinases. Other anticancer approaches such as abrogation of the G₂ DNA damage checkpoint also relies on forcing cells into mitosis. Thus understanding mitotic catastrophe may uncover principles of tumorigenesis as well as insights for novel therapeutic designs.

Mitotic Catastrophe

Historically, the term 'mitotic catastrophe' was first used (Russell and Nurse, 1987) to describe the lethal phenotype associated with the fission yeast strain that contain an activated allele of *cdc2* (*cdc2-3w*) and a recessive temperature-sensitive *wee1* mutation (*wee1-50*) (Russell and Nurse, 1986). These mutations overactivate the mitotic engine, resulting in premature and aberrant mitosis, particularly with respect to chromosome segregation and septum formation (Molz *et al.*, 1989).

Mitotic catastrophe has since been used for cell death associated with inappropriate entry into mitosis. Because the term 'mitotic catastrophe' has been adopted rather loosely in the literature, there are disagreements about the precise causes, mechanisms, and outcomes of the process. Some studies adopted a relatively simple definition to mean a mode of cell death associated with aberrant mitotic activity (Vakifahmetoglu *et al.*, 2008). More recent attempts to standardize different types of cell death defined mitotic catastrophe to be associated with aberrant mitotic activity that ultimately triggers cell death or irreversible cell cycle arrest (Galluzzi *et al.*, 2012). In this

definition, cell death can occur either during or after the defective mitosis.

One of the better characterized events that lead to mitotic catastrophe is when cells are challenged with antimitotic drugs. Under these conditions, cells typically undergo prolonged mitotic arrest. Whether this and other abnormal mitotic events represent mitotic catastrophe depends on the eventual fate of the cells (Figure 1). On the one hand, some cells are able to divide and continue to propagate (many cancer cells, in particular, can tolerate certain number of mis-segregated chromosomes). These types of impaired mitosis are not generally regarded as mitotic catastrophe. On the other hand, cells that undergo cell death during the aberrant mitosis are generally regarded as undergoing mitotic catastrophe. Mitotic catastrophe is also applicable when cells lose growth capacity after exiting the aberrant mitosis. For example, after a prolonged block in mitosis, some cells can exit mitosis without chromosome segregation through mitotic slippage. These interphase cells can then either undergo cell death or enter a permanent senescence-like arrest state.

A major challenge for studying mitotic catastrophe is to be able to distinguish it from cells undergoing normal mitosis or other forms of cell death. It should be noted that the events leading to cell death are decisive for determining if a cell undergoes mitotic catastrophe. A major drawback of endpoint analyses such as apoptosis assays is that they do not provide information on the history of the cell before cell death. Temporal information obtained from approaches such as time-lapse imaging is paramount in establishing if cell death is a direct consequence of mitosis.

Inducing Mitotic Catastrophe

Unscheduled Entry into Mitosis

Cyclin-dependent kinase 1 (CDK1) is the major protein kinase that drives cells into normal mitosis. CDK1 is activated by binding to B-type cyclins (mainly cyclin B1), which then phosphorylates substrates critical for entry into mitosis. Destruction of cyclin B1 provides a mechanism to rapidly inactivate CDK1 and allow the cell to exit mitosis (Fung and Poon, 2005).

CDK1 is present throughout the cell cycle. In contrast, cyclin B1 accumulates and forms a complex with CDK1 after entering S phase. The complex is kept inactive before mitosis by MYT1 and WEE1 through phosphorylation of CDK1^{Thr14/Tyr15}. At the end of G₂ phase, the stockpile of inactive cyclin B1-CDK1 is activated abruptly by members of the CDC25 phosphatase family. Cyclin B1-CDK1 catalyzes its own activation by simultaneously stimulating CDC25 activation and WEE1 inactivation (Lindqvist *et al.*, 2009). This bistable system is believed to be kick-started by PLK1, initiating the activation of CDC25 and inactivation of WEE1/MYT1

Figure 1 Different cell fates can occur after aberrant mitosis. Aberrant mitosis can give rise to multiple cell fates. Cell death can occur during the mitotic block (mitotic catastrophe). Alternatively, cells can exit mitosis without division by mitotic slippage, forming tetraploid cells (typically containing multiple nuclei). These cells can then undergo cell death or permanent cell cycle arrest (mitotic catastrophe). However, tetraploid cells can also re-replicate the DNA and centrosomes (red dots), entering another round of mitosis. Depending on the levels of defects during mitosis, it is possible that mitotic cells can perform cell division relatively normally (top of the diagram). Cell death or arrest can occur in the daughter cells (not shown in the diagram) and the process can also be regarded as mitotic catastrophe.

(van Vugt and Medema, 2005). The activation of PLK1 in turn requires phosphorylation of PLK1^{Thr210} by Aurora A, an event that is assisted by Bora. Binding of Bora to PLK1 is stimulated by cyclin B1-CDK1-dependent phosphorylation, creating yet another positive feedback loop in the activation of CDK1 (Lindqvist *et al.*, 2009).

To maintain genome stability, it is vital to prevent mitotic entry before DNA replication or DNA repair is completed. Several checkpoints participate in monitoring DNA integrity and prevent precocious entry into mitosis. It is now clear that similar underlying principles are involved in these checkpoints to prevent the activation of CDK1 (Kastan and Bartek, 2004).

Following exposure to ionizing radiation or other genotoxic insults that elicit DNA double-strand breaks, ATM is autophosphorylated on Ser1981, leading to release of active monomers from homodimer complexes. The ATM-related kinase ATR is activated by a broader spectrum of stress including hypoxia and replication stress. ATM/ATR then phosphorylates residues in the SQ/TQ domain of CHK1/CHK2, thereby stimulating the activity of these effector kinases (Smith *et al.*, 2010).

Stalled replication forks, which can be induced by insufficient nucleotide supply or lesions and obstacles on the DNA, mainly activate the ATR-CHK1 pathway. This pathway is essential even in the absence of exogenous stress during unperturbed S phase, probably for maintaining high rates of replication fork progression (Petermann and Caldecott, 2006).

Once the ATM/ATR-CHK1/CHK2 cascade is activated, CDK1 activity is suppressed by inhibitory phosphorylation (Chen and Poon, 2008). CHK1 phosphorylates and activates

WEE1 by promoting 14-3-3 binding. In addition, CHK1/CHK2 also represses all three isoforms of the CDC25 phosphatase family. Specifically, phosphorylation of CDC25C by CHK1/CHK2 inactivates its phosphatase activity both directly and indirectly through the creation of a 14-3-3 binding site. Binding of 14-3-3 masks a proximal nuclear localization sequence and anchors CDC25C in the cytoplasm, preventing efficient access of CDC25C to its substrate cyclin B1-CDK1. CDC25B, which possesses a unique role in activating cyclin B1-CDK1 at the centrosome, is also inactivated by 14-3-3 binding following CHK1-dependent phosphorylation. Finally, CDC25A is targeted for rapid degradation by SCF ^{β -TrCP}-dependent ubiquitination after CHK1-dependent phosphorylation. Collectively, these mechanisms suppress CDK1 activity when DNA replication or repair is not completed.

It is anticipated that untimely mitosis from distinct periods of the cell cycle may exert different effects on mitotic catastrophe. While normal G₁ cells probably contain insufficient cyclin B1-CDK1 complexes to support precocious mitosis, cells in S phase start to accumulate cyclin B1. Stimulating mitosis in cells with incompletely replicated DNA should generate extensive defects in chromosome segregation. Similarly, the presence of unrepaired DNA damage should affect mitosis profoundly. Conceptually, it is less clear if mitotic catastrophe is induced by accelerating G₂ cells into mitosis.

Uncoupling of the DNA integrity checkpoints promotes unscheduled entry into mitosis. It has become increasingly clear that mitotic catastrophe is a major outcome of unscheduled mitosis (Chan *et al.*, 1999; Castedo *et al.*, 2004; Vogel *et al.*, 2007). Cells that possess defective checkpoints,

such as those derived from ataxia-telangiectasia, often exhibit radio-resistant DNA synthesis and mitotic catastrophe (Lavin and Khanna, 1999). Since the ultimate effect of the checkpoints is an accumulation of CDK1 inhibitory phosphorylation, it is not surprising that expression of a non-phosphorylatable mutant of CDK1 can also trigger mitotic catastrophe (Blasina *et al.*, 1997; Niida *et al.*, 2005; Chow *et al.*, 2003).

Agents that target components of the ATM/ATR–CHK1/CHK2 axis can induce mitotic catastrophe. Indeed, a number of these small-molecule inhibitors are promising anticancer agents (Furgason and Bahassi *et al.*, 2013). The spindle-assembly checkpoint is required for mitotic catastrophe induced by abrogation of the DNA integrity checkpoints (On *et al.*, 2011; Nitta *et al.*, 2004; Vogel *et al.*, 2004; Chen *et al.*, 2012), suggesting that a trap in mitosis is indispensable for these types of cell death.

Mitotic Block

At the end of mitosis, cyclin B1 is removed by a ubiquitin ligase called the anaphase-promoting complex/cyclosome (APC/C) loaded with the targeting subunit CDC20 (Yu, 2007). Activated cyclin B1–CDK1 catalyzes its own destruction by stimulating the activity of APC/C^{CDC20}. APC/C^{CDC20} is also responsible for degrading several proteins that are important for mitotic exit. For example, degradation of securin by APC/C^{CDC20} releases separase, which in turn cleaves cohesin to facilitate sister chromatid separation (Yanagida, 2000). Proteolysis of geminin releases CDT1, enabling CDT1 to form the pre-replication complex required for the next round of DNA replication (Seo and Kroll, 2006).

Activation of APC/C^{CDC20} is initiated only when all the chromosomes have achieved bipolar attachment to the mitotic spindles. Unattached kinetochores or the absence of tension between the paired kinetochores activates a surveillance mechanism termed the spindle-assembly checkpoint (Figure 2). This checkpoint inhibits APC/C^{CDC20}, thereby

maintaining a high concentration of active cyclin B1–CDK1 (Musacchio and Salmon, 2007).

Mechanistically, unattached kinetochores attract the components of the checkpoint machinery (including BUB1, BUB3, MAD1, MAD2, MAD3/BUBR1, MPS1, and CENP-E), catalyzing the formation of a diffusible mitotic checkpoint complex (MCC, components include MAD2, BUBR1, and BUB3), which in turn inhibit APC/C^{CDC20}. The binding to CDC20 involves a conformational change in MAD2 from a less stable open conformation (known as O-MAD2) to the more stable close conformation (C-MAD2). According to a currently favored MAD2-template model, the conversion of O-MAD2 to C-MAD2 is autocatalytic, supporting the cytosolic propagation of the checkpoint signal away from the kinetochores (Musacchio and Salmon, 2007). Once all the kinetochores are properly attached, the spindle-assembly checkpoint is silenced (through mechanisms that are still not clearly defined) to enable APC/C^{CDC20} activation and mitotic exit.

In normal mitosis, the dynamic nature of microtubules facilitates efficient capturing of kinetochores by the spindles. Moreover, incorrectly attached kinetochores (such as both kinetochores of a chromosome are attached to the same spindle pole) are corrected through mechanisms that monitor tension between paired kinetochores. However, genetic alterations of components of spindle formation or the spindle-assembly checkpoint can result in severe delay in mitosis.

Agents that suppress microtubules dynamics can also lead to protracted activation of the spindle-assembly checkpoint (Weaver and Cleveland, 2005). These include chemicals that attenuate microtubules depolymerization (e.g., Taxol) or polymerization (e.g., vinca alkaloid). The stabilization of APC/C targets and persistent activation of cyclin B1–CDK1 ensure that the cell remains in mitosis. Other antimitotic chemicals that target essential mitotic regulators such as Aurora A, PLK1, or the kinesin Eg5 (KIF11) can also trigger protracted mitotic arrest.

The responses to prolonged mitotic block vary greatly between different cancer cell lines as well as between individual

Figure 2 Regulation of mitotic exit by APC/C^{CDC20}. During early mitosis, APC/C^{CDC20} is stimulated by cyclin B–CDK1. But concurrently, the activity of APC/C^{CDC20} is suppressed by the spindle-assembly checkpoint (MAD2). The checkpoint is activated by either the presence of unattached kinetochores or the absence of tension between paired kinetochores. Once all kinetochores are properly attached (metaphase), the spindle-assembly checkpoint is silenced to enable APC/C^{CDC20} activation. APC/C^{CDC20} then targets several proteins including cyclin B1 and securin to ubiquitin-mediated degradation. Proteolysis of securin releases separase, which in turn cleaves cohesin to promote sister chromatid separation and anaphase.

cells from the same cell line (Gascoigne and Taylor, 2008). Cells can either execute cell death directly during mitosis or undergo mitotic slippage. During mitotic slippage, cyclin B1–CDK1 is downregulated precociously and cells exit mitosis without chromosome segregation and cytokinesis. The nuclear envelope then reforms randomly around groups of chromosome. In this connection, the resulting micronucleation after mitotic slippage has been used in some studies as one of the morphological features associated with mitotic catastrophe.

The central event of mitotic slippage appears to be a slow but continuous degradation of cyclin B1 (Brito and Rieder, 2006). Whether a cell dies during prolonged mitotic block is believed to be determined by a competition between the slow degradation of cyclin B1 (which affects the rate of mitotic slippage) and the activation of cell death pathways (accumulation of death activators or loss of death inhibitors). Hence cell death during mitotic arrest is the consequence of the cell breaching the death threshold before the mitotic slippage threshold is reached.

Although mitotic cell death is prevented immediately by mitotic slippage, the G_1 cells generated are less fit to propagate than normal cells. Mitotic slippage generates cells containing tetraploid DNA contents and two centrosomes, both of which can be further duplicated during the subsequent S phase. As centrosomes are microtubule organization centers, there is a possibility that cells with supernumerary centrosomes can form multipolar spindles during the subsequent mitosis. The uneven segregation of genetic material into daughter cells precipitates different cell fates, including mitotic catastrophe, aneuploidy, and transformation (Storchova and Kuffer, 2008).

It has been proposed that after mitotic slippage, a p53-dependent ‘tetraploidy checkpoint’ that detects abnormal number of chromosomes or centrosomes is activated and prevents S phase entry. However, the existence of the tetraploidy checkpoint has been disputed. The fact that many cells undergo p53-dependent cell cycle arrest or apoptosis after mitotic slippage is likely to be due to DNA damage or centrosomal stress during the aberrant mitosis (Hayashi and Karlseder, 2013).

Mechanisms of Mitotic Catastrophe

Mitotic catastrophe involves cell death or arrest during or after a defective mitosis. Although cell death during mitotic catastrophe frequently displays a phenotypic characteristic of apoptosis and shares several molecular hallmarks with apoptosis such as caspase activation, there is evidence that it can also occur by necrosis (Vakifahmetoglu *et al.*, 2008).

The molecular basis of cell death during mitotic catastrophe remains incompletely understood. As discussed above, whether cell death occurs during mitosis is likely to be determined by a competition between the slow degradation of cyclin B1 and the accumulation of cell death signals. There is good but not definitive evidence that cyclin B1–CDK1 activity is involved in activating the death signals. While the underlying principles of CDK1-mediated toxicity remain largely unresolved, a few targets that affect survival have been identified. For example, several members of the B-cell lymphoma 2 (BCL-2) family are phosphorylated by cyclin B1–CDK1.

Phosphorylation of Bcl-2-associated death promoter (BAD) by cyclin B1–CDK1 reduces the interaction with 14-3-3, allowing BAD to translocate to mitochondria and induce cell death (Berndtsson *et al.*, 2005; Konishi *et al.*, 2002). BCL-2 is also phosphorylated by cyclin B1–CDK1, but the role in mitotic catastrophe remains to be clarified (Brichese *et al.*, 2002; Furukawa *et al.*, 2000; Ling *et al.*, 1998; Scatena *et al.*, 1998). B-cell lymphoma-extra large (BCL-XL) is phosphorylated by cyclin B1–CDK1, leading to the inactivation of its anti-apoptotic activity (Terrano *et al.*, 2010; Sakurikar *et al.*, 2012). Finally, cyclin B1–CDK1 also phosphorylates the anti-apoptotic protein MCL-1, inducing the rapid degradation of MCL-1 in an APC/C^{CDK20}-dependent manner (Harley *et al.*, 2010; Chu *et al.*, 2012).

If there are large gaps in our knowledge regarding the mechanisms of mitotic cell death, even less is known about the mechanisms tipping the balance toward cell death after mitotic slippage. The DNA damage or centrosomal stress generated during the aberrant mitosis is likely to be responsible for activating p53 (Hayashi and Karlseder, 2013). This at least explains the apoptosis and senescence after mitotic slippage in cells containing wild-type p53.

An important implication is that cells that evade mitotic catastrophe can enter a tetraploidy G_1 state. If additional checkpoints are not present (such as being p53 defective), aneuploid cells can further undergo DNA replication and centrosome duplication, paving the way to multipolar mitosis and further genome instability. It is likely that the ability to execute cytokinesis reduces as the ploidy increases, giving rise to multinucleated giant cells (King, 2008).

The presence of polyploid giant cells that fail to be killed by mitotic catastrophe may also account for resistance to cancer therapy. For example, following DNA damage, many polyploid cells appear after an initial phase of mitotic catastrophe and survive for weeks as mono- or multinucleated giant cells (Blagosklonny, 1999). Although whether giant cells still retain proliferative potential is controversial, there is evidence that they can undergo multipolar mitosis to return to near diploid state (Erenpreisa and Cragg, 2001). These studies suggest that the multistep process of escaping mitotic catastrophe through polyploidization followed by depolyploidization may account for tumor relapse after initial efficient cancer therapy.

Concluding Remarks

Mitotic catastrophe is characterized by an unscheduled or prolonged activation of mitotic drivers followed by cell death. In some cases, permanent cell cycle arrest following the aberrant mitosis is also regarded as an outcome of mitotic catastrophe. Causes of mitotic catastrophe include unscheduled entry into mitosis from interphase or prolonged mitotic arrest caused by the activation of the spindle-assembly checkpoint.

Addressing the outstanding issues concerning mitotic catastrophe, including the various conditions that can trigger the process, mechanisms that regulate cell death and mitotic slippage, and the genetic determinants that modulate various cell fates will transform our understanding of both tumorigenesis and antimitotic drug treatments.

Autophagy refers to the group of cellular processes that mediate degradation of intracellular components in lysosomes and the subsequent recycling of their constituents (Mizushima *et al.*, 2008). As such, autophagy shares a common final compartment with endocytosis and phagocytosis, the lysosome. Continuous turnover of intracellular proteins and organelles allows for their renewal and serves as a mechanism for quality control of newly synthesized cellular structures. Furthermore, the regulated balance between synthesis and degradation of proteins and organelles permits for rapid modification of their cellular levels to accommodate to environmental changes.

Historically, the discovery of autophagy was temporally close to that of lysosomes, the subcellular compartment with higher content of hydrolases in the cell (Ohsumi, 2014). Protein degradation by autophagy was initially linked mainly to nutritional changes. Starvation or conditions in which nutrients become scarce often lead to maximal activation of autophagy to facilitate recycling of intracellular components for anabolic purposes. Although nutrient deprivation is one of the best characterized activators of autophagy, better understanding of the molecular basis of the autophagic pathways and the development of tools and markers that permit tracking flux of substrates through the autophagic system have revealed that autophagy is activated in response to a multiplicity of stimuli ranking from cellular stressors (oxidative stress, DNA damage, mitochondria depolarization, etc.) to extracellular cues and inputs (growth factors, cytokines, pathogens, etc.). This better understanding of the conditions associated with autophagy activation, and direct studies analyzing the consequences of upregulating or downregulating autophagy in whole organisms have unveiled the participation of autophagy in an impressive number of cellular functions: energetic balance quality control, cell and tissue remodeling, cell differentiation, cellular defense, innate immunity, cell death, cellular senescence, among others (Green and Levine, 2014; Kenific and Debnath, 2015; Marino *et al.*, 2014). The multiple physiological roles of autophagy along with the connection of autophagy malfunctioning to common human disorders (neurodegeneration, diabetes, muscle waste, infectious diseases, etc.) have motivated the recent interest in the understanding of the autophagic processes at the molecular level (Jiang and Mizushima, 2014; Schneider and Cuervo, 2014).

Autophagic Pathways

Differences in the molecular effectors that contribute to delivery of cargo (material to be degraded) into lysosomes are the bases for the distinction among autophagic pathways. When cargo is sequestered in double membrane vesicles in the cytosol that then acquire the hydrolases required for degradation through lysosomal fusion, autophagy is referred to as macroautophagy (Yang and Klionsky, 2010; Figure 1). In the case of

microautophagy, cargo is directly sequestered through invaginations or tubulations of the lysosomal or late endosomal membrane and are released into the lumen of these organelles after pinching off (de Waal *et al.*, 1986; Figure 2). Not all forms of autophagy require vesicles for cargo sequestration; for example, in chaperone-mediated autophagy (CMA) cytosolic proteins reach the lysosomal lumen upon translocation across the lysosomal membrane (Kaushik and Cuervo, 2012; Figure 3). Different variants have already been described for each of these mechanisms of cargo delivery to lysosomes.

Studies in yeast were key for the identification of a subset of about 35 genes (ATG or autophagy-related genes) that participate in the process of macroautophagy as well as some microautophagy specific genes, whereas the characterization of CMA and some specialized forms of macro- and microautophagy was performed in mammalian cells. For simplicity we will use the mammalian nomenclature for all the autophagy-related genes in this entry.

Autophagy Step-by-Step

Induction of Autophagy

Although multiple signaling mechanisms lead to activation of macroautophagy, the better characterized is the mammalian target of rapamycin (mTor) signaling pathway, closely linked to starvation-induced autophagy. The energy-sensing kinase complex target of rapamycin complex 1 (TORC1) displays maximal activity in the presence of nutrients, leading to the phosphorylation and sequestration of ULK1, a kinase required for autophagy initiation (Kanazawa *et al.*, 2004; Hara *et al.*, 2008; Figure 1). Upon deprivation of nutrients, inactivation of mTOR results in release of ULK1 and its localization at the sites of autophagosome formation. The limiting membrane of these organelles forms through combination of proteins and lipids from different cellular compartments such as the endoplasmic reticulum (ER), mitochondria, plasma membrane, Golgi, and sorting endosomes. In all these cases, the area in the membrane from where the limiting membrane or phagophore originates is 'marked' through phosphorylation of lipids in these membranes. Besides ULK1, Vps34 is the second lipid kinase commonly recruited to sites of autophagosome biogenesis as part of the Beclin/Vps15/Vps34 complex (Figure 1). Elongation of the membrane occurs through two ubiquitin-like conjugation processes (Ichimura *et al.*, 2000): conjugation of two proteins Atg12 to Atg5 and conjugation of a protein LC3 to the lipid phosphatidylethanolamine. A common ligase, Atg7, is shared by both conjugation events. Tethering of Atg16L-enriched micelles with conjugate LC3 also contributes to growth of the limiting membrane (Ravikumar *et al.*, 2010).

The first signaling mechanism identified for CMA was through the retinoid-acid receptor alpha that acts as an endogenous repressor of this pathway (Anguiano *et al.*, 2013).

Figure 1 Macroautophagy and selective macroautophagy variants. Left: simplified schematic of the steps of macroautophagy and protein complexes that modulate some of these steps. Right: types of selective macroautophagy.

Figure 2 Yeast and mammalian microautophagy. Left: yeast microautophagy occurs at the vacuole membrane in a multistep process that allows for cargo recognition, formation of the microphagy membrane apparatus (MIPA), and internalization into single-membrane vesicles that pinch off and are subsequently degraded. Right: in mammals, microautophagy has only been described in late endocytic compartments, where cargo can be sequestered in bulk or selectively enriched upon hsc70 binding in vesicles formed in these membranes through assembly of the ESCRT proteins.

Recently, studies in T cells have unveiled activation of CMA by reactive oxygen species (ROS)-dependent signaling through the calcineurin–NFAT (nuclear factor of activated T cells) axis (Valdor *et al.*, 2014). The signaling mechanism that initiates microautophagy remains unknown.

Cargo Recognition

Macroautophagy was considered an ‘in bulk’ process in which all the cytosolic components present in the area surrounding

the site of autophagosome biogenesis were sequestered at once. However, the selectivity of this process has now been demonstrated after the identification of a subset of proteins, cargo receptors, that have the ability to simultaneously bind to cargo molecules and Atg proteins (Stolz *et al.*, 2014). This dual recruitment facilitates formation of the limiting membrane selectively around mitochondria (mitophagy), peroxisomes (pexophagy), lipid droplets (lipophagy), ribosomes (ribophagy), pathogens (xenophagy), aggregates (aggrephagy), etc. (Figure 1). Some of these cargo receptors, p62 or NBr1, are

Figure 3 Chaperone-mediated autophagy. Schematic of the main steps of CMA. Upon recognition of the targeting motif by hsc70, the protein-chaperone complex is targeted to the lysosomal membrane where it binds to LAMP-2A and induces the multimerization and formation of the translocation complex. After substrate unfolding, the luminal chaperone completes translocation of the substrate.

shared among these processes due to their ability to recognize common tagging molecules such as ubiquitin (Novak and Dikic, 2011). A pair of cytosolic chaperones, hsc70 and Bag1, can also serve as cargo recognition molecules for aggregate proteins in a variant of conventional macroautophagy known as chaperone-assisted selective autophagy (CASA) (Arndt *et al.*, 2010).

In yeast microautophagy, sequestration of cytosolic components such as peroxisomes (micropexophagy), nucleus (piecemeal autophagy), or pathogens (microxenophagy) by the invaginations at the vacuole membrane occurs at specific contact sides through interaction of cargo and vacuole membrane proteins (Sakai *et al.*, 1998; Roberts *et al.*, 2003). Although microautophagy has not been described in mammalian cells, a similar process of invagination and internalization in single-membrane proteins occurs in the late endocytic compartment/multivesicular bodies and has been named endosomal microautophagy (e-MI) (Sahu *et al.*, 2011). Both in bulk and selective targeting of cytosolic proteins by hsc70 occur through e-MI (Figure 2).

Recognition of the cytosolic proteins that undergo degradation by CMA is mediated by binding of hsc70 to a pentapeptide motif in the protein sequence biochemically related to KFERQ (Dice, 1990). Mutagenesis of this targeting motif abolishes CMA of the protein, and addition of this pentapeptide sequence to proteins that usually do not undergo degradation by CMA reroutes them toward this pathway, supporting that this motif is necessary and sufficient for

targeting to CMA. Binding of hsc70 to this region is also required for selective e-MI of cytosolic proteins, but addition of this motif is not sufficient to drive e-MI of a protein (Sahu *et al.*, 2011; Figure 3).

Lysosomal Delivery

After sealing of the limiting membrane to form a double membrane vesicle in a SNARE (soluble *N*-ethylmaleimide-sensitive factor attachment protein receptor)-mediated manner, the autophagosome moves through microtubules tracks, often toward the perinuclear region, to meet the lysosomes (Moreau *et al.*, 2011). Kiss-and-run events infuse part of the lysosomal hydrolases in autophagosomes forming a hybrid acid compartment known as autolysosome, where cargo is degraded.

In the case of microautophagy, delivery occurs through vesicles in the surface of the vacuole (forming a structure known as MIPA) in yeast, or through assembly of a series of protein complexes known as endosomal sorting complexes required for transport (ESCRT) proteins in the surface of the late endosome (in mammals). ESCRT proteins are well known because of their ability to form multivesicular bodies in the late endosomes for membrane protein degradation (Figure 2). Whether the two degradative processes, of cytosolic proteins and of plasma membrane proteins, occur in dedicate multivesicular bodies for each purpose or if they occur simultaneously in the same compartments remains unknown.

Once the complex hsc70/cytosolic proteins targeted for CMA reaches the lysosomal membrane they bind to the cytosolic tail of the lysosome-associated membrane protein type 2A (L2A) that is a spliced variant of the LAMP-2 gene. Substrate binding induces multimerization of L2A to form a 700 kDa complex required for protein translocation after unfolding (Cuervo and Dice, 1996; Bandyopadhyay *et al.*, 2008; Figure 3). Translocation also requires a luminal chaperone, a variant of cytosolic hsc70, but whether this chaperone is required for actual pulling of substrates inside lysosomes or just to prevent their retrotranslocation to the cytosol is not known. Translocation complexes are highly dynamic structures that deassemble into monomeric units of L2A right after the substrate crosses the lysosomal membrane, to allow a new cycle of binding and translocation. Chaperones in the cytosolic side of the lysosomal membrane are required for substrate unfolding and they also assist in L2A disassembly, whereas chaperones in the luminal side of the membrane participate in substrate translocation and contribute to maintain L2A stability when transitioning between monomers and multimeric complexes (Bandyopadhyay *et al.*, 2008; Figure 3).

Recycling, an Integral Part of Autophagy

The autophagy process does not end with the degradation of the cytosolic material in the lysosomal lumen; instead, both cargo and functional lysosomal components can be retrieved out of the autolysosome. Permeases dedicated to cytosolic export of amino acids and sugars have been identified in the vacuole membrane in yeast (Sekito *et al.*, 2008). Less is known about the mammalian lysosome permeases but specific amino

acid transporters have been known to exist in this membrane for a long time. Recycling of cargo components helps sustain cellular anabolic processes even in the absence of nutrients. Since the three autophagic pathways share the lysosome as a common site of degradation, these permeases and transporters also recycle amino acids from proteins degraded by CMA and microautophagy. In the case of e-MI, the cargo internalized in the multivesicular bodies can be degraded either in these late endosomes, transferred for lysosomal degradation, or exported extracellularly as exosomes upon fusion of lysosomes with the plasma membrane (Figure 2).

Lysosomal components can also be retrieved out of the lysosome into vesicles or tubules that form at the limiting membrane of the lysosome and then pinch off to constitute the basis of a new cargo-free lysosome. Vesiculation, tubulation, and sorting of lysosomal membrane proteins and enzymes into these structures is regulated by a family of lipid kinases that act in a coordinate manner with clathrin and motor proteins that bind to areas of vesicle formation (Yu *et al.*, 2010). This recycling is maximally activated after starvation conditions, when a large fraction of lysosomes has fused to autophagosomes.

Autophagy-Related Cellular Compartments

As described in the previous section, the cellular compartments that participate in macroautophagy are well characterized and include the phagophore or limiting membrane, autophagosomes, autolysosomes, and lysosomes. Autophagosomes can also fuse first with late endosomes, forming an amphisome, where extra- and intracellular material converge to ultimately reach the lysosome through endosome/lysosome fusion (Fengsrud *et al.*, 2000). Autophagic flux occurs, to some extent, even in the absence of *de novo* synthesis, thanks to a reservoir of Atg protein complexes already assembled but that remain in an inactive state through sequestration in different cellular compartments such as acetylated microtubules or plasma membrane connexins, in the case of the Beclin/Vps34 complexes (Geeraert *et al.*, 2010; Bejarano *et al.*, 2014), or lysosomal TORC1, in the case of ULK1 (Kanazawa *et al.*, 2004; Hara *et al.*, 2008). Whenever autophagy activation occurs, these complexes can be readily released and relocate to sites of autophagosome formation to contribute to formation of the limiting membrane. Sustained activation of autophagy requires an expansion of the lysosomal pool to meet the autophagic needs, which is attained in part through the above-mentioned recycling of lysosomal components out of autolysosomes, and in part through activation of *de novo* lysosomal biogenesis. In fact, most of the genes that code for lysosomal proteins and for Atgs are under the control of a family of transcription factors that recognizes a CLEAR motif in the promoter region of these genes. The first and best characterized member of this family is the transcription factor EB (TFEB) that is normally retained in the cytosol through phosphorylation by different kinases, including the TORC1 complex that sits in the surface of lysosomes (Settembre *et al.*, 2011). Amino acids exported from lysosomes maintain TORC1 active, TFEB phosphorylated, and the autophagic/lysosomal transcriptional program attenuated. However, when rates of degradation through lysosomes decrease, the absence of exiting

amino acids leads to TORC1 inactivation and the consequent reduced phosphorylation of TFEB facilitates its nuclear translocation and the activation of the transcriptional program responsible for autophagy and lysosome biogenesis. A newly identified member of this family, TFN3, seems to also undergo lysosomal mTOR phosphorylation and activate the lysosomal/autophagic program through comparable mechanisms (Martina *et al.*, 2014). The most ubiquitous distribution of TFN3 and its presence in organs such as the central nervous system, where levels of TFEB are negligible, support a more generalized regulatory role for this new protein.

Mammalian microautophagy has only been demonstrated so far in late endosomes/multivesicular bodies, compartments shared with endocytosis. However, the impact of expanded or reduced endocytic flux in e-MI remains unknown.

CMA occurs in a specific lysosomal subpopulation that bears in its lumen the lysosomal hsc70 chaperone required for substrate translocation. CMA-active lysosomes are secondary lysosomes that still retain the ability to fuse with autophagic and endocytic vesicles, although less efficiently than other lysosomal subgroups (Cuervo *et al.*, 1997). They correspond to the most acidic group of lysosomes, since lys-hsc70 is more stable at acidic pH and slight reduction in luminal acidification is sufficient to induce its rapid degradation. Rather than biogenically independent lysosomal subgroups, CMA lysosomes and lysosomes engaged in other vesicular processes rapidly convert into each other allowing for expansion or shrinkage of the pool of lysosomes most efficient for each autophagic pathway on demand.

The Autophagic Cargo and Purpose of Its Degradation

Activation of macroautophagy during starvation in yeast and mammals was considered necessary to replenish the intracellular pool of amino acids and sustain synthesis of proteins required for adaptation to starvation. However, more recently, macroautophagy has shown the capability to promote degradation of energetically more favorable molecules such as lipids and glycogen. Degradation of lipid droplets (lipophagy) starts with the formation of the limiting membrane *in situ*, as lipid droplets also contribute lipids for autophagosome biogenesis. This membrane sequesters a whole or a portion of lipid droplets and delivers them to lysosomes through autophagosome/lysosome fusion (Singh *et al.*, 2009). The lipases in the lysosomal lumen break down lipid droplet triglycerides into free fatty acids that, once exported from the lysosome, are oxidized in the mitochondria to generate energy. A similar process mediates degradation of glycogen stores into lysosomes upon autophagic sequestration (Kotoulas *et al.*, 2006).

Macroautophagy can also degrade portions or whole organelles such as mitochondria, ER, peroxisomes, and even lysosomes. Continuous basal degradation of organelles contributes to their renewal. Furthermore, selective macroautophagy can be activated to: (1) eliminate organelles when they are damaged or do no longer function, such as depolarized mitochondria or leaking lysosomes; (2) regulate the size of pool of cellular organelles and modulate their function, such as excess of peroxisomes or mitochondria; and (3) allow

for cellular differentiation or cell-type conversion, such as elimination of organelles in reticulocytes as they convert into red cells, or elimination of the spermatozoid mitochondria preovule fecundation (Singh and Cuervo, 2011).

Degradation of cytosolic content by macroautophagy is often used as a mechanism of cellular defense, such as activation of xenophagy, to eliminate pathogens that reach the cytosol or of aggrephagy to eliminate protein aggregates that could become toxic when accumulating inside cells (Levine, 2005).

Specialized regions of the plasma membrane are also targeted for autophagic degradation, often with regulatory purposes. For example, macroautophagy can have an impact in cell-to-cell communication, through degradation of connexins/gap junctions or of neuronal dendritic spines and synaptic components; it can also impact cellular motility through degradation of motile cilia (ciliophagy), environmental sensing through degradation of the primary cilia components, or cell adhesion through degradation of adhesion foci, all present at the plasma membrane.

Yeast microautophagy can also degrade proteins, organelles, and pathogens, but the reasons why this pathway is chosen in specific conditions over macroautophagy remain unknown. Mammalian endosomal microautophagy has only shown so far to degrade cytosolic proteins, but contrary to CMA, unfolding is not a prerequisite for their degradation through this pathway, making it potentially suitable for the elimination of oligomeric proteins before they consolidate into large aggregates.

Specific characteristics of cargo delivery by CMA make this pathway only suitable for degradation of single-soluble proteins that can undergo complete unfolding. In principle, all the CMA substrates come from the cytosol in order to bind the cytosolic tail of L2A. Thus, degradation of organelle proteins by CMA only occurs if these proteins relocate to the cytosol or after their *de novo* synthesis before they reach their final compartment. An example of this type of CMA degradation has been recently observed in a transgenic mouse model unable to perform CMA in the liver, where nuclearly encoded mitochondria enzymes accumulate in part in the cytosol but also inside the mitochondria due to their reduced degradation through CMA (Schneider *et al.*, 2014). This observation opens the intriguing possibility of CMA contributing to regulate the mitochondria enzymatic load. The fact that CMA substrate proteins should bind to the cytosolic tail of the receptor makes this pathway unsuitable for degradation of membrane proteins, at least as far as they are integrated in membranes, since retrotranslocation will not be possible in that case. However, it is possible that the CMA degradation recently proposed for a plasma membrane receptor occurs as quality control before membrane insertion of this protein, or that degradation of this type of proteins by CMA is preceded by a membrane-extraction step, comparable to the one proposed for chaperones before the degradation of membrane proteins by AAA proteases. Soluble cytosolic proteins, the canonical CMA cargo, undergo degradation through this pathway both with regulatory purposes or as a mechanism for protein quality control. CMA has been recently demonstrated to contribute to regulation of glucose and lipid metabolic pathways in the liver (Schneider *et al.*, 2014) and to the proteome remodeling

required for T cell activation, since selective degradation of specific subsets of proteins by CMA reduces their intracellular levels, and subsequently their function (Valdor *et al.*, 2014). The role of CMA in protein quality control has been well demonstrated during oxidative stress where CMA allows targeting of only oxidized forms of the proteins without affecting functional ones.

Pathophysiology of Autophagy

The multiplicity of functions attributed to the autophagic process speaks to their already proven physiological relevance. Although studies in unicellular models and mammalian cells in culture have been key to understanding the interplay of autophagy with other cellular processes, importance of proper autophagy functioning at the whole organism level has been inferred from genetically modified mouse models. Animals with whole body blockage of macroautophagy are born, but die few hours after birth, due to their inability to adapt to the starvation period that precedes lactancy (Kuma *et al.*, 2004). Tissue-specific conditional knockout mouse models for specific Atg have offered a better understanding of organ-specific functions of macroautophagy. Thus, complete loss of macroautophagy in the liver leads to accumulation of damaged organelles, lipids (steatosis), and liver dysfunction, whereas blockage of macroautophagy in specific areas of the brain leads to early neurodegeneration with accumulation of intraneuronal ubiquitinated protein aggregates that end killing neuronal cells (Komatsu *et al.*, 2005; Hara *et al.*, 2006). Blockage of autophagy in cardiomyocytes, when inflicted early in life, is well tolerated and defective cardiac function can only be elicited upon stress. However, blockage of autophagy in the heart of an adult animal progresses rapidly to heart failure (Nakai *et al.*, 2007). These regulatable models in which autophagy is eliminated at different times in life support the existence of early compensatory mechanisms in response to macroautophagy failure that are lost with aging. Elimination of macroautophagy genes in specific cell types has also connected autophagy to innate and acquired immunity, pancreatic beta-cell homeostasis and insulin secretion, muscle atrophy after immobilization, among others. These models are also revealing Atg functions independent of autophagy as in the case of Atg16L function in the Paneth cells of the intestine (Cadwell *et al.*, 2008). Overexpression of Atg proteins have been a successful approach to increase life span and health span in invertebrates. Although, to date, only one mouse model expressing a copy of Atg5 has been generated, analysis of life span in this model has revealed an encouraging increase (Pyo *et al.*, 2013). Future studies are needed to discriminate the specific functions of macroautophagy responsible for this life-span extension.

Studies on CMA are now also taking advantage of conditional transgenic mouse models with reduced CMA by selectively eliminating the exon that encodes for the L2A variant. Blockage of CMA in the liver leads to major metabolic aberrations and organism problems in metabolism of lipids and glycogen (Schneider *et al.*, 2014). Although none of these macromolecules can be degraded by CMA, many of the enzymes that regulate these metabolic pathways have been

validated as bona fide CMA substrates. Failure to undergo degradation by CMA in this model leads to an increase in their intracellular levels and the subsequent aberrant increase in function. Mouse models with defective CMA in T cells have shown that this autophagy pathway is required for the proteome changes that lead to the T-cell activation program (Valdor *et al.*, 2014). Failure to degrade inhibitory proteins of this program prevents T cell activation in the CMA-incompetent animals. Interestingly, studies in the T cell model have also revealed that the reduction in CMA with age in these cells is behind their functional failure in old organism (immuno-senescence) and that restoration of L2A in old T cells to the levels observed in young animals makes them functional again. Similar expression of an exogenous copy of L2A in mouse liver is sufficient to restore liver homeostasis and function.

Considering this extensive array of physiological functions attributed to autophagy, it was expected that malfunctioning of autophagy underlies the basis of severe human disorders (reviewed in detail elsewhere (Cuervo and Macian, 2014; Jiang and Mizushima, 2014; Lee, 2014; Martin *et al.*, 2015; Schneider and Cuervo, 2014)).

Concluding Remarks

The field of autophagy has undergone major expansion during the last two decades that has resulted in important paradigm shifts in this area. Although much remains to be discovered on the basis of selectivity, autophagy is no longer considered an in-bulk nonselective process. Instead, multiple autophagy variants have emerged and selective removal of specific cellular components is being identified. Furthermore, autophagy is no longer a process for destruction of unwanted cellular material, but rather a fine-tuned mechanism that contributes to maintain cellular homeostasis through selective degradation and recycling. Much is left to learn about the regulation of the different types of autophagy, the rules of their cellular co-existence, and about how their activities are coordinated in the context of disease to compensate one for another. It is precisely this connection between autophagy and human disease that has motivated the growing interest in the developing of efficient ways to manipulate the autophagic process with therapeutic purposes.

AKT Serine-threonine kinase activated by PI3K.

AMPK Serine-threonine kinase activated by AMP.

BRCA1,2 Breast cancer tumor suppressor genes 1 and 2.

ERK Serine-threonine kinase activated by MEK.

FYN Cytoplasmic tyrosine kinase of the SRC family.

LKB Serine-threonine kinase, enhancer of AMPK activity.

MEK Multi-specificity kinase activated by RAF.

mTOR Serine-threonine kinase indirectly activated by AKT.

MYC Transcription factor.

NF1 GAP for RAS-GTP.

PTEN Lipid (PI-3) phosphatase.

PTP1B Cytosolic protein tyrosine phosphatase.

PTPN11 RTK phosphatase.

RAF Serine-threonine kinase activated by RAS-GTP.

RAS Small guanine nucleotide binding protein.

RB Retinoblastoma tumor suppressor – transcriptional regulator.

SRC Cytoplasmic tyrosine kinase.

TP53 Tumor suppressor and transcription factor.

Introduction: Scope and Intent of Article

Over the past five decades, the concept that mutation of discrete cellular genes can drive the formation and progression of human cancers has evolved. These genes, termed oncogenes and tumor suppressor genes, constitute a defining paradigm for our understanding of cancer biology. The elucidation of their function in both normal and malignant cell physiology has provided a rational platform for the development of therapeutic strategies to treat the many forms of the disease. This article provides a brief overview of (1) the role of oncogenes and tumor suppressor genes in human cancers, (2) how the functional interaction between proteins encoded by oncogenes and tumor suppressor genes alters normal cellular

processes such as proliferation, metabolism/energetic, and cell survival, and (3) the role of oncogenes and tumor suppressor genes in diseases other than cancer, namely human developmental syndromes.

Oncogenes and Tumor Suppressor Genes and Human Cancer

During the first half of the twentieth century, two parallel tracks of research emerged to provide evidence for mutations of defined genes as major causes of cancer: one was the identification of animal viruses that induced rapid formation of cancers in chickens and rodents (retroviruses), and the other

was the discovery of chemical compounds that caused mutations in cellular genes (carcinogens), which would in turn promote cancer formation. In the 1970s these two lines of research merged, when it was discovered that tumor-forming retroviruses carried mutated genes (oncogenes) that were derived from normal cellular genes (proto-oncogenes) (Bishop, 1983, 1985), and that human cancers contained mutated proto-oncogenes that arose in the absence of any known viral etiology (Barbacid, 1987). These findings gave rise to the concepts that cancers can derive from multiple mechanisms and by mutation of one or more cellular genes.

As cancer cell biologists started to catalogue and compare the properties of normal and cancer cells, it became clear that cancer cells exhibited a set of cellular and physical properties, known as the 'transformed' phenotype, that were distinct from normal cells (e.g., altered morphology, unrestricted cell growth, altered metabolism, and multiple and varied chromosomal aberrations). Surprisingly, it was observed that if one 'fused' a normal cell with a cancer cell, the resultant hybrid cell containing a complete complement of host and donor chromosomes exhibited a 'normal' cellular phenotype (Harris *et al.*, 1969; Stanbridge, 1976). Acquisition of the 'transformed' phenotype required the loss of certain cellular chromosomes from the normal host, leading to the idea that certain normal cellular genes could 'suppress' the tumorigenic properties of cancer cells. Hence the concept of tumor suppressor genes emerged in the cancer literature.

Identification of Specific Oncogenes and Tumor Suppressor Genes in Human Cancers

Oncogenes

'Genes that, when activated by mutation, increase the selective growth advantage of the cell in which they reside.'

One of the first oncogenes to be discovered is harbored in the chicken retrovirus, Rous sarcoma virus, that was first described by Peyton Rous in the early 1900s (Martin, 2004). This virus causes transformation of avian and rodent cells in cell culture and induces tumors in birds and rodents. The oncogenic powers of Rous sarcoma virus reside in the viral gene denoted SRC, which is not truly a viral gene but a mutated form of a cellular gene denoted c-SRC, present in all vertebrate species (Stehelin *et al.*, 1976). This discovery led to the hypotheses that retroviruses can 'capture' and mutate cellular genes during their replication in host cells and that expression of these mutated cellular genes during subsequent rounds of host cell infection is sufficient to induce transformation of cells and tumor formation. This discovery led immediately to the realization that expression of other cellular genes altered by carcinogens or X-rays may mimic the effects of virus infection and lead to cancer formation.

Evidence that human cancers contain oncogenes came from observations that introduction of DNA purified from human cancer cells induced the transformation of normal rodent cells (Krontiris and Cooper, 1981; Perucho *et al.*, 1981; Shih and Weinberg, 1982). The molecular characterization of one of the genes responsible for this transformation unveiled a mutated version of the cellular RAS gene, which was found to encode a protein that exhibited constitutive enzymatic activity,

providing the first clue that oncogenes, of either viral or cellular origin exhibit unregulated activities (see below).

Tumor suppressor genes

'Genes that, when inactivated by mutation, increase the selective growth advantage of the cell in which they reside.'

In human cancers, inactivation of tumor suppressor genes occurs via two prominent mechanisms, loss of a defined region of a chromosome leading to complete loss of protein expression or expression of truncated forms of the protein, or mutations within a tumor suppressor gene altering protein function (Hinds and Weinberg, 1994; Weinberg, 1991). Direct evidence for the former in human cancer emanated from the study of retinoblastoma, a rare, inheritable, childhood tumor of the eye. Genetic studies showed that tumors arising in afflicted children either lack the RB gene or carry a mutated form of it. The RB gene encodes a transcription regulator (pRB) involved in normal growth control (see below) (Hollingsworth *et al.*, 1993). Subsequent genetic studies have identified a number of inheritable cancers that are linked to the loss of function of defined cellular genes (e.g., Wilm's tumor and the NF1 gene, familial adenomatous polyposis and the APC gene) (Cichowski and Jacks, 2001; Fearon and Vogelstein, 1990).

The gene encoding the p53 protein, TP53, is an example of how mutations alter normal protein function, leading to tumor initiation and progression (Hinds and Weinberg, 1994; Rivlin *et al.*, 2011; Vousden and Prives, 2009). TP53 is a transcription factor that regulates a cell's response to stress by inducing cell cycle arrest, DNA repair, or apoptosis, or by regulating cell metabolism. The importance of p53 in human cancers is underscored by the fact that a very large number of human cancers exhibit TP53 mutations and by the finding that the Li-Fraumeni syndrome, a rare cancer predisposition syndrome, is characterized by germline mutations in TP53. Interestingly, studies of rodent and human oncogenic DNA viruses have revealed that normal p53 function is neutralized in virus-infected cells by binding to discrete virus-encoded proteins. For example, the binding of the human papilloma virus-encoded protein, E6, to p53 inhibits p53 activity and is essential for human papilloma virus transformation of human cells (Moody and Laimins, 2010).

Number of mutations in a human cancer

In the past 10 years, genome-wide DNA sequencing has cataloged millions of mutations that arise in different human cancers. For example, solid tumors of the colon, breast, brain, or pancreas display somatic mutations that are predicted to alter the structure of as many as 60–70 proteins (Vogelstein *et al.*, 2013; Wood *et al.*, 2007). Interestingly, some tumors, such as melanomas and lung cancers, contain significantly more somatic mutations (approximately 200), consistent with the well-documented roles of the carcinogens, UV light, and cigarette smoke, in the etiology of these cancers.

How do we know which mutations are important for development and progression of a given cancer? It has been suggested that mutated genes which confer selective growth to the cancer are referred to as 'driver' genes, whereas mutations that do not affect function are referred to as 'passenger' mutations. An analysis of more than 18 000 mutated genes

containing over 400 000 subtle mutations in over 3000 tumors has defined 125 'driver' genes (Vogelstein *et al.*, 2013). Of these, 54 appear to function as oncogenes and 71 as tumor suppressor genes. Interestingly, a large number of these genes were previously identified as oncogenes or tumor suppressor genes using more classical approaches.

Functional Roles of Key Oncogene and Tumor Suppressor Gene Products

Oncogenes and tumor suppressor genes regulate the balance between cell proliferation, metabolism and energetics, and cell survival. They do this by encoding proteins that transmit signals from the extracellular milieu, which in turn stimulates the transcriptional apparatus of the cells. The changes in gene expression mediated by such intracellular signals trigger the synthesis of a host of cellular proteins that drive cell cycle progression, modulate the metabolic and energetic state of the cell, and control cell death. Some of the most important pathways regulated by oncogenes and tumor suppressors are briefly described below.

Transmission of extracellular cues

The ability of cells to sense and respond to their environmental milieu is dependent on a wide variety of transmembrane cell surface receptors. One class of such receptors, the receptor tyrosine kinases (RTKs), specifically engages ligands, such as polypeptide growth factors, cytokines, and hormones, with high affinity and transmits signals dependent on this binding to the inside of cells, thus initiating a cascade of biochemical reactions (pathways) that control the cell's response to its environment (Hubbard and Miller, 2007; Figure 1(a)). In the human genome over 50 unique genes encode RTKs, including receptors for the epidermal growth factor (EGF), platelet-derived growth factor, fibroblast growth factor, vascular endothelial growth factor (VEGF), hepatocyte growth factor/scatter factor, and insulin/insulin-like growth factors (IGF). Because of their central roles in promoting cell proliferation, many RTKs have been implicated as etiological agents in various cancers, either through receptor gain-of-function mutations (EGFRs) or through receptor/ligand over-expression (EGFR, VEGFR, IGF) (Blume-Jensen and Hunter, 2001). In cancer cells, the mutational activation of RTKs and/or their over-expression lead to elevated and constitutive downstream signaling, resulting in uncontrolled cell proliferation (Hubbard and Miller, 2007).

The RAS pathway

The RAS pathway (Figure 1(a)) is a major intracellular signaling pathway in normal and cancerous cells of adult organisms and developing embryos alike (Bos, 1989). It is activated downstream of RTKs by guanine nucleotide exchange proteins (GEFs), which mediate the exchange of guanine nucleotide diphosphate (GDP) for guanine nucleotide triphosphate (GTP) on the small G protein, RAS (Bos *et al.*, 2007). Once activated by GTP, RAS stimulates the catalytic activity of the serine/threonine protein kinase RAF (Dhillon *et al.*, 2007). GAPs (GTPase-activating proteins) promote the return of RAS to the inactive GDP-bound state (McCormick, 1989).

Activated RAF leads to the stimulation of a multi-specificity kinase, MEK, which in turn phosphorylates and activates the serine/threonine kinase, ERK. Activated ERK translocates to the nucleus, where it catalyzes the phosphorylation of a myriad of nuclear substrates, including transcription factors, transcriptional regulatory proteins, and other substrates involved in DNA replication and cell division. RAS proteins were among the first oncogenes to be identified, and mutated RAS is found in about 15% of human cancer (Davies *et al.*, 2002). Mutation of RAF occurs in 60–70% of malignant melanomas and at a lower frequency in a wide range of other human cancers (Davies *et al.*, 2002). Interestingly few, if any, mutations in MEK or ERK have been identified in human cancers.

The PI3K pathway

A second important signaling pathway coupled to RTK activation is the phosphatidylinositol-3-kinase (PI3K) pathway (Cantley, 2002; Figure 1(b)). PI3Ks are lipid kinases that play central roles in cell cycle progression, apoptosis, DNA repair, and cellular metabolism. PI3Ks transduce signals from cell surface receptors by generating phosphorylated phosphatidylinositols, which in turn activate effector kinase pathways, principally those involving AKT and mTOR (Figure 1). These pathways play key roles in promoting cancer cell survival and proliferation (Cantley, 2002; Osaki *et al.*, 2004). The activity of the PI3K pathway in normal cells is tightly regulated by the phosphatidylinositol-3,4,5-trisphosphate 3-phosphatase, PTEN (phosphatase and tensin homolog deleted from chromosome 10). PTEN dephosphorylates phosphatidylinositol-3,4,5-trisphosphate, thereby negatively regulating signaling through all the downstream targets of PI3K, including AKT and mTOR (Chalhoub and Baker, 2009; Di Cristofano and Pandolfi, 2000; Osaki *et al.*, 2004). In human cancers the deregulation of the PI3K signaling pathway is linked to the development of approximately one-third of human cancers (Samuels and Waldman, 2010). Somatic mutations in the PTEN gene are among the most prevalent of these genetic changes (Yin and Shen, 2008).

Transcriptional regulation

Oncogenes encode a large repertoire of transcription factors, which can be activated by chromosomal rearrangements, gene fusions, gene amplifications, and to a lesser extent somatic mutations. A prime example is the MYC oncogene (Dang, 2012). Altered expression of the MYC gene occurs in over half of human cancers (Vita and Henriksson, 2006). In many cancers the level of MYC becomes elevated as a consequence of chromosomal rearrangements that place the MYC gene under the control of a constitutively activated promoter, such as an immunoglobulin gene promoter (Burkett's lymphoma). MYC can also be the direct target of signal transduction pathways activated by RTKs in response to nutrients, growth factors, and mitogenic stimuli. ERK, the downstream effector of the RAS/RAF/MEK/ERK pathway, stabilizes MYC protein by phosphorylation (Gustafson and Weiss, 2010), thus preventing its turnover within the nucleus. Thus activation of this pathway either by RTK activation or mutation of RAS or RAF can lead to the stabilization of MYC and increased transcription of MYC target genes (Figure 1(a)).

Figure 1 Key intracellular signaling pathways regulated by oncogenes and tumor suppressor genes. (a) Growth factor/mitogen binding to cell surface receptors (RTKs) leads to intracellular activation of the RAS-RAF-MEK-ERK pathway which culminates in transcriptional stimulation of genes required for cells to advance through the cell cycle. Progression through the cell cycle is dependent upon the activities of cyclin-CDKs which are needed for movement through 'restriction' points. Many pathways that stimulate the cell to divide are populated with oncogenes whose actions are counteracted by tumor suppressors (notably pRB and p53) (see text for details). The balance between these two classes of cell cycle regulators determines whether a cell completes division. (b) Growth factor/mitogen binding to RTKs also stimulates the PI3K pathway, which leads to the activation of AKT-mTOR and stimulation of protein synthesis. AKT and mTOR also play major roles in metabolism by regulating intracellular levels of glucose and AMP/ATP ratios. Filled ovals denote oncogenes, and filled rectangles represent tumor suppressors.

Interplay between Oncogenes and Tumor Suppressor Genes in Human Cancer

In cancer, the activation of oncogenes and compromised function of tumor suppressor genes alter the finely tuned balance between positive and negative signals that regulate cell proliferation, metabolism, and cell survival. This section describes key examples of how proteins encoded by oncogenes and tumor suppressor genes functionally interact with one another, the effects these interactions have on normal

physiological processes of the cell, and how the changes in such processes provide a growth advantage to the cancer cell.

Oncogenes, Tumor Suppressor Genes, and Cell Cycle Regulation

Cell proliferation is a highly controlled process that involves passage through the four main phases of the cell cycle (Ho, 2009): (1) G1, or interphase, during which cellular constituents (other than DNA) are increased in preparation for the

generation of two new daughter cells, (2) S phase, DNA synthesis, (3) G₂, the second interphase stage in which the integrity of the newly synthesized DNA is ascertained, among other things, and (4) M phase (mitosis) in which equal distribution of cellular components into two daughter cells and cell division takes place. To pass from one phase to another, the cell must traverse one or more checkpoints (Weinberg, 2007). Not unexpectedly, these checkpoints are frequent sites of regulation by proteins encoded by oncogenes and tumor suppressor genes. If cells exit the cell cycle, they assume a resting or quiescent state, termed G₀. The majority of cells in adult organisms, cells that form the fully differentiated organs of the human body, reside in the G₀ state. When injury occurs and/or cell replacement is needed, growth factors (such as those that activate RTKs) initiate the exit of cells from G₀ into G₁ and their continued presence is required for passage through the first checkpoint within G₁ (termed the restriction point).

Ligand activation of growth factor receptors stimulates intracellular signaling cascades (Figure 1(a)), which culminate in new gene transcription. Among the genes activated by this process is the cyclin D gene family, which is expressed in early G₁. Cyclin D binds and activates the cyclin-dependent protein kinases (cdks), 4 and 6, which phosphorylate pRB, leading to the release of the transcription factor, E2F, and progression through the cell cycle. pRB is a transcriptional repressor that blocks progression through early to mid-G₁ and must be inactivated by phosphorylation for passage through the mid-G₁ restriction point. Specifically, in early G₁, unphosphorylated pRB binds to and inhibits the transcription factor, E2F. Phosphorylation of pRB by cyclinD/cdk4/cdk6 leads to the release of E2F and renders E2F active transcriptionally. E2F, in turn, stimulates production of cyclin E, which binds and activates cdk2. The cyclin E/cdk2 complex completes inactivation of Rb by fully phosphorylating it, thereby allowing the cell to complete G₁ and enter S phase.

In cancer, pRB is inactivated by deletion/mutation or by DNA tumor viruses, such as papillomaviruses, which produce viral proteins that bind and sequester pRB (Moody and Laimins, 2010), leading to the release of E2F and activation of the transcriptional machinery. Without pRB functioning as the gate-keeper of the early checkpoint, cancer cells are free to divide without submitting themselves to quality controls throughout G₁. Such a situation fosters accumulated mistakes in DNA replication (S phase), uncontrolled growth, and tumor development. Although pRB itself is rarely mutated in human cancers, its pathway is dysregulated in a large majority of patients, stressing the importance of the pathway to oncogenesis. One of the most common alterations is overexpression of Cyclin D, cdk 4 and cdk 6. Furthermore, growth factor pathways are frequently hyperactivated in the same cells that harbor pRB pathway disruptions, resulting in amplified dysregulation of G₁ transit.

The transcription factor p53 monitors the strength and/or fidelity of events related to cell cycle progression, including strength of oncogenic signaling, hypoxia, DNA damage, and transcription (Weinberg, 2007). When abnormalities are sensed, a variety of pathways can trigger signals that increase levels of p53 (Harris, 1996). In turn, p53 activates pathways that regulate whether the cell should arrest progression while

repairing cellular damage (DNA) or undergo programmed cell death or apoptosis. If the cell is able to repair the abnormality sensed by p53, it can reenter and complete the cell cycle or enter a state of dormancy/senescence from which it does not return. When damage is too great for the cell to survive, p53 initiates apoptosis.

The TP53 gene is the most commonly mutated tumor suppressor in human cancers, a testament to its importance. Loss of p53 function results in continual cycling of cells even in the presence of metabolic imbalances, DNA damage, and transcriptional irregularities, giving rise in many instances to cells that accumulate mutations in key cell signaling pathways, that harbor chromosomal abnormalities and that have altered their metabolic equilibrium – all hallmarks of malignancy.

Oncogenes, Tumor Suppressor Genes and Cell Metabolism

Fully differentiated, nondividing cells have low nutrient requirements and derive the majority of their ATP from catabolism of glucose to pyruvate, which is further processed through the TCA cycle and the electron transport chain (oxidative phosphorylation) (Vander Heiden *et al.*, 2009). In contrast, rapidly dividing cells (normal or cancerous) have high nutrient requirements and an increased need for synthesis of macromolecules (proteins, RNA and DNA, carbohydrates, and complex lipids) to support cell division (Figure 2(a)). To satisfy these needs, rapidly dividing cells take up more glucose and glutamine than nondividing cells, and process them through glycolysis and glutamine catabolism, thereby generating both ATP and macromolecules, and reducing their dependence on oxidative phosphorylation. Cancer cells accomplish this conversion from oxidative phosphorylation to glycolysis even in the presence of high oxygen tension, termed aerobic glycolysis, a hallmark of the Warburg effect. Oncogenes and tumor suppressor genes antagonistically regulate this conversion through altered production of catabolic and anabolic enzymes, posttranslational modifications, and protein–protein interactions (Dang and Semenza, 1999; Iurlaro *et al.*, 2014). We will briefly discuss three examples of such genes, namely, PI3K, MYC, and p53.

The PI3K pathway

AKT, a major effector of PI3K (Figure 1(b)), is an important stimulator of the tumor glycolytic phenotype. Activation of AKT increases the expression and translocation of glucose transporters, phosphorylation of key glycolytic enzymes, and activation of mTOR through phosphorylation of negative inhibitors of mTOR (Cairns *et al.*, 2011). The serine/threonine kinase mTOR, in turn directly stimulates mRNA translation and new protein synthesis by phosphorylating/activating S6 kinase and phosphorylating/inactivating 4EBP1. Through an indirect transcriptional mechanism, mTOR also increases levels of HIF1 (Denko, 2008), a key sensor of oxygen levels and a transcription factor whose levels are augmented under hypoxic conditions, conditions frequently observed in centers of human tumors. HIF1 increases synthesis of multiple glycolytic enzymes, thereby significantly contributing to the conversion from oxidative phosphorylation to glycolysis.

Figure 2 Oncogenes and tumor suppressor genes in metabolism and cell survival/apoptosis. (a) Glycolysis and oxidative phosphorylation (OXPHOS) are major pathways for energy generation, principally via the utilization of glucose and glutamine. The major points of regulation by oncogenes (ovals) and tumor suppressors (rectangles) are indicated (see text for details). (b) Cell survival is mediated by two major pathways, the extrinsic pathway, which is stimulated by extracellular death ligands, and the intrinsic pathway, which is activated by intracellular cues that regulate the balance between pro- and anti-apoptotic Bcl-2 family proteins. In normal cells, RTK signaling upregulates anti-apoptotic Bcl-2 family proteins, whereas the tumor suppressors p53 and pTEN upregulate the activity of pro-apoptotic Bcl-2 family members. In cancer cells, the normal control of these pathways is perturbed (see text for details). Filled ovals denote oncogenes, and filled rectangles represent tumor suppressors.

mTOR also plays a central role in the integration of growth factor signals and nutrient availability through regulation by adenosine monophosphate activated kinase (AMPK), a sensor of adenosine triphosphate (ATP) concentrations available to the cell (Figure 1(b)). A high AMP:ATP (Hardie, 2007) ratio activates AMPK, which then inactivates mTOR, thereby shifting

from glycolysis to ATP production through the oxidative phosphorylation pathway. AMPK activity itself is positively regulated by LKB1, a tumor suppressor mutated in liver and lung cancers. LKB1 is a serine-threonine kinase that phosphorylates AMPK to enhance its negative effect on mTOR (Shaw et al., 2004). Thus the LKB1/AMPK axis functions

in opposition to PI-3 kinase to regulate cellular energetics. Mutation of LKB1 and high levels of oncogenic signaling can override the negative control of LKB1/AMPK through hyperactivation of PI3K, permitting cells to divide under unfavorable energetic conditions.

MYC

The MYC oncogene regulates cell metabolism in multiple ways, including increased expression of enzymes involved in glutamine metabolism (Dang and Semenza, 1999; Figure 2(a)). MYC also collaborates transcriptionally with HIF1 to elevate levels of glucose transporters and glycolytic enzymes, thereby, reinforcing glycolysis, particularly under hypoxic conditions. Under normoxic conditions, HIF1 protein levels are reduced by oxygen-dependent hydroxylation and ubiquitination, mediated in part by the tumor suppressor, von Hippel–Lindau (VHL) protein, a ubiquitin ligase. Thus, HIF1 is regulated positively by oncogenes such as tyrosine kinases and MYC and negatively by VHL (Kim and Dang, 2006).

TP53

The tumor suppressor p53 plays a major role in regulating metabolism largely through its transcriptional activity (Levine and Puzio-Kuter, 2010). In normal cells, p53 helps to maintain appropriate levels of signaling proteins and metabolic enzymes that favor oxidative phosphorylation and limit glycolysis (Figure 2(a)). In cancer cells that harbor p53 mutations, conversion from oxidative phosphorylation to the glycolytic phenotype is favored. Specifically, mutated p53 results in increased expression of glucose transporters, enhanced nucleotide biosynthesis, and reduced synthesis of cytochrome *c* oxidase and negative regulators of PI3K. Thus, the rigorous control p53 exercises over metabolism in normal cells (opposing growth factor action) is diminished in cancer cells by mutational inactivation, which permits conversion of the cell to a metabolic phenotype that favors rapid growth.

Oncogenes, Tumor Suppressor Genes, and Apoptosis

Oncogenes and tumor suppressor genes play major roles in determining whether cells survive or die by regulating the balance between pro-survival and apoptosis-inducing pathways, regulated by the Bcl-2 family (Adams and Cory, 2007). This large family of genes (total of 25) can be either pro-apoptotic (e.g., Bax, Bad, Bak, and Bok) or anti-apoptotic (e.g., Bcl-2, Bcl-xL, and Bcl-w) and together regulate the major pathways (extrinsic and intrinsic) that activate apoptosis (Figure 2(b)). Members of this family of proteins associate with one another at the mitochondrial membrane and regulate the organelle's redox potential and membrane permeability. An overabundance of pro-apoptotic proteins at the membrane results in pore formation, release of cytochrome *c* into the cytoplasm, formation of the apoptosome, and activation of the apoptotic process. Pro-survival oncogenes, such as growth factors, their receptors, and components of their signaling pathways, increase levels of anti-apoptotic Bcl-2 family members, whereas tumor suppressors, such as p53, PTEN, and IGF-1 binding proteins, increase levels of pro-apoptotic family members.

Another function of pro-survival oncogenes is to activate the PI3K and NF κ B pro-survival pathways. PI3K activation leads to AKT phosphorylation and inactivation of the Bad, caspase 9, and I κ B pro-apoptotic proteins (Manning and Cantley, 2007), whereas NF κ B activation leads to enhanced expression of many pro-survival genes, most notably Bcl-2 (Cogswell *et al.*, 2000). PI3K and NF κ B effects are opposed by PTEN and I κ B, respectively. The tumor suppressor p53 can directly induce apoptosis if the cell has incurred too much damage to divide (Fridman and Lowe, 2003). This is accomplished by transcriptionally regulating many pro-apoptotic genes, such as increasing expression of the Fas death-inducing receptor, IGFBP3 (which sequesters IGF-1 and prevents it from binding its receptor), Bax (which oligomerizes and induces cytochrome *c* release from the mitochondria), and NOXA (which binds and inhibits the anti-apoptotic protein Bcl-2). P53 also inhibits the expression of pro-survival genes, such as Smac/DIABLO, which bind and inhibit inhibitors of apoptosis (IAPs). Finally, p53 can act by directly binding members of the Bcl-2 family to promote apoptosis (Haupt *et al.*, 2003). Loss of p53 function in cancer can lead to survival of cells that have sustained multiple mutations and damage, thereby permitting unregulated growth.

Role of Oncogenes and Tumor Suppressor Genes in Human Developmental Diseases

Sustained proliferative signaling resulting from activated oncogenes and inactivated tumor suppressor genes are fundamental traits of cancer. However, oncogenes and tumor suppressors also play important roles during embryonic development, as highlighted by the diverse set of human syndromes resulting from congenital mutations affecting not only the predisposition to neoplasms but also bone growth, neurodegeneration, and glucose homeostasis.

Developmental Syndromes of RAS-ERK and PI3K-AKT Dysregulation

Noonan/LEOPARD, neurofibromatosis type1, PTEN hamartomatous, and Proteus/Cowden syndromes are autosomally inherited familial syndromes that involve members of the RAS-ERK or PI3K-AKT signaling pathways (Figure 3(a)). Dysregulation of these pathways during embryonic development and neural crest differentiation results in common features, including craniofacial dysmorphism, cardiac malformations and cutaneous, musculoskeletal and ocular abnormalities, neurocognitive delay, and in some syndromes a predisposition to the development of cancer.

Noonan syndrome

Noonan syndrome (NS) is an autosomal dominant disorder that is characterized by postnatally reduced growth, distinctive craniofacial features, congenital cardiac defects, bleeding disorders, and variable cognitive deficits (Tartaglia *et al.*, 2011). Mutation of *PTPN11*, which encodes the non-receptor protein tyrosine phosphatase SHP2, accounts for the majority of cases. SHP2 is a negative regulator of RTKs and the RAS-ERK pathways, which when mutated and inactivated in NS patients

Figure 3 Oncogenes and tumor suppressor genes in developmental and metabolic disorders. (a) Developmental abnormalities associated with the RAS-ERK and PI3K-AKT pathways. Components of the RAS-ERK and PI3K-AKT pathways activated downstream of RTK are dysregulated in various human developmental syndromes. (b) Factors that affect the FYN-LKB1-AMPK pathway regulation of cellular metabolism and diabetes. The FYN-LKB1-AMPK pathway activity is increased by diverse factors, such as low circulating glucose, sedentary lifestyle, and AICAR (an analog of AMP and activator of AMPK) to regulate multiple metabolic processes. See text for details.

leads to increased signaling through the RAS-ERK pathway (Keilhack *et al.*, 2005). *SOS1* missense mutations are the second most common cause of NS occurring in approximately 13% of cases. *SOS1* is a RASGEF that becomes mutationally activated in NS, resulting in increased GTP-bound Ras and enhanced downstream signaling (Roberts *et al.*, 2007).

Neurofibromatosis

The main characteristics of Neurofibromatosis type1 (NF1) include cutaneous, subcutaneous and plexiform neurofibromas,

café-au-lait spots, and Lisch nodules in the iris. Changes of the skeletal system, vascular defects, learning disabilities, poor social skill, and predisposition for the development of malignant neoplasia are also observed (Friedman and Birch, 1997). NF1 is caused by heterozygous loss-of-function mutations or deletions of the *NF1* gene, encoding a GTPase-activating protein that functions as a negative regulator of RAS GTPase. Loss of NF1 results in hyperactivation of Ras signaling pathways, which contributes to the development of the defects observed in neurofibromatosis.

PTEN-opathies

Germline mutations of the tumor suppressor, PTEN, have been identified in patients with diverse clinical features ranging from overgrowth to malignancy that are collectively classified as PTEN hamartomatous syndromes (PHS). These include Cowden syndrome (CS) and Bannayan–Riley–Ruvalcaba syndrome (BRRS).

AKT1 and PIK3CA mutations in Proteus and Cowden syndrome

Approximately 11% of CS patients carry germline AKT1 or PI3K mutations. Cell lines generated from patients that have these mutations display increased phosphorylation of AKT1 and PIP3 levels, providing evidence that mutation of AKT1 or PI3K is a predisposition for CS (Orloff *et al.*, 2013). An activating AKT1 mutation was also found to cause Proteus syndrome (Lindhurst *et al.*, 2011), characterized by segmental overgrowth of the brain, bone, skin, and other tissues.

Overall, the relatively high prevalence of some of these disorders and the frequency of defects in RAS-ERK and PI3K-AKT signaling associated with them suggest that these pathways represent one of the most common events affecting the developmental process.

Oncogenes and Tumor Suppressor Genes in Neurodegenerative Diseases

In mammals, most neurons are generated before birth, but it is now well accepted that neurogenesis continues into adulthood. Accumulating evidence indicates that impaired neurogenesis is associated with dysregulation of oncogenic signaling pathways and tumor suppressor function leading to development of diseases, such as Alzheimer's and Parkinson's diseases. In these neurodegenerative disorders, one of the main etiological features is enhanced cell death, accompanied by dysregulation of the tumor suppressor, p53.

Parkinson's disease

In Parkinson's disease (PD) the main locus of degeneration is a small area in the ventral midbrain, the *pars compacta* of the substantia nigra that is mostly composed of dopaminergic neurons (Barzilai and Melamed, 2003). PD-affected substantia nigra harbors intracellular inclusions named Lewy bodies containing α -synuclein. Autosomal dominant inherited cases of PD are linked with mutations in α -synuclein that abrogate its ability to protect neuronal cells challenged with pro-apoptotic effectors by lowering p53 expression and transcriptional activity (da Costa *et al.*, 2000). Transgenic mice expressing α -synuclein with the pathogenic A53T mutation exhibit accumulation of p53 in the mitochondria and induction of cell death, suggesting a critical role of p53 in the development of the disease (Giaime *et al.*, 2006).

Several lines of evidence indicate that proteins associated with autosomal recessive cases of PD also functionally interact with p53. PD cases of recessive inheritance result from mutation in three genes encoding parkin, PINK-1, or DJ-1. Parkin physically interacts with the p53 promoter and represses p53 transcription (da Costa and Checler, 2010). Mutation of Parkin prevents repression, allowing elevated transcription of p53 and induction of apoptosis. Mutations in DJ-1 also result

in accumulation of p53, as well as p53's transcriptional target Bax (Fan *et al.*, 2008).

Alzheimer's disease

The pathology of Alzheimer's disease (AD) is characterized by two histological lesions, the senile plaques and the neurofibrillary tangles. The severity of these lesions correlates with the level of cognitive decline. Tangles result from the intracellular accumulation of hyperphosphorylated tau protein, while senile plaques are extracellular deposits mainly due to the aggregation of various hydrophobic amyloid- β peptides (Mandelkow, 1999; Masters *et al.*, 1985). That cell death in AD is p53-dependent is supported by several observations. APP-derived fragments can modulate p53 by directly transactivating its promoter. Additionally, oxidative DNA damage induces the extracellular translocation of APP, concomitantly with increased p53 mRNA levels. Finally, in both mouse models of AD and in AD brains, neurons with altered morphology display both APP and p53 accumulation (Ohya *et al.*, 2005). Comparison of p53 immunoreactivity in postmortem AD-affected brains revealed a consistent increase in p53 expression in the temporal cortex areas as compared to normal controls (Kitamura *et al.*, 1997). The increased expression of p53 coincides with increased DNA fragmentation and Fas expression, indicating that p53 can contribute to cell death in AD brains (de la Monte *et al.*, 1997).

The tumor suppressors p21, p27, PTEN, and BRCA1 have also been implicated in the pathology of neurodegenerative disease. BRCA1, for example, co-localizes with neurofibrillary tangles. Analysis of clinically normal, aged brain tissue also revealed less BRCA1 than in cases of AD. This finding suggests that neurofibrillary tangles of normal aging differ in origin from those present in neurodegenerative disease. In addition to the suppression of cell cycle, BRCA1 is implicated in the maintenance of genomic integrity. In cells with BRCA1 deletion, a loss of telomere repeats was observed, a feature present in degenerating neurons of AD (McPherson *et al.*, 2006). Studies of patients and animal models of PD have also demonstrated a direct role for PTEN in neurodegeneration associated with oxidative stress. Oxidative stress in rat hippocampal cells leads to mitochondrial accumulation of PTEN resulting in the induction of apoptosis. Conversely, knockdown of PTEN prevents neuronal apoptosis (Morris *et al.*, 2010).

Oncogenic signaling pathway activation leading to aberrant cell cycle entry of terminally differentiated neuronal cells has been proposed as a model of pathogenesis in neurodegenerative disorders. Cell cycle reentry driven by adenoviral-expression of c-MYC and RAS oncogenes in post-mitotic primary cortical neurons leads to tau protein phosphorylation and conformational changes similar to those observed in AD (McShea *et al.*, 2007). Evidence of cell cycle reentry is also present in mutant APP and tau transgenic mice, occurring prior to the development of pathological features such as neurofibrillary tangles and senile plaques (Lee *et al.*, 2009).

Oncogenes and Tumor Suppressor Genes in Diabetes

Type 2 diabetes mellitus (T2DM) is a metabolic disorder characterized by hyperglycemia and altered lipid metabolism

due to peripheral insulin resistance and defects of insulin secretion by pancreatic islet β -cells. The insulin receptor activates multiple downstream pathways to control energy homeostasis; however, the PI3K-AKT pathway is considered its major effector. The insulin-independent LKB1-AMPK pathway also contributes to metabolic control. Dysfunction of these pathways can lead to impaired glucose homeostasis and diabetes.

PI3K-AKT pathway

Genetic defects in loci encoding insulin pathway components, transcription factors or rate-limiting enzymes of glucose metabolism account for only 1–5% of diabetes cases (Permutt *et al.*, 2005). Nonetheless, the effects of the genetic alterations in insulin signaling downstream of PI3K-AKT has been extensively studied. For example, the amino acid substitution R409Q in the catalytic p85 α subunit of PI3K has been shown to compromise insulin-stimulated PI3K activity, while the mutation R274H within the AKT2 kinase domain results in severe autosomal dominant insulin resistance. This substitution greatly impairs AKT kinase activity and functions in a dominant-negative fashion to inhibit adipocyte differentiation *in vitro*. As is the case in humans, mice lacking AKT2 are insulin resistant, hyperglycemic, and hyperinsulinemic (George *et al.*, 2004). Conversely, mice lacking negative regulators of PI3K-AKT signaling exhibit improved glucose homeostasis. Both PTP1B (a phosphoserine-phosphothreonine phosphatase) deficiency and PTEN hemizygosity lead to improved glucose tolerance and insulin sensitivity in mice (Elchebly *et al.*, 1999; Wong *et al.*, 2007).

LKB1-AMPK pathway

Although some cases of obesity and T2DM result from genetic dysfunction, the increased incidence of these disorders is strongly correlated with sedentary lifestyle and over-nutrition. Dietary changes and regular exercise are the first therapies for the management of T2DM. However, when lifestyle modifications are insufficient to control serum glucose and lipid levels, drugs that increase insulin action and/or induce body energy consumption are used for treatment. Two commonly used drugs that potentiate insulin action, metformin and thiazolidinediones, have been shown to activate the LKB1-AMPK pathway (described above; Figure 3(b)).

AMPK activity is increased during exercise and could, at least in part, mediate the favorable effects of physical activity on insulin sensitivity, lipid and glucose utilization in skeletal muscle, adipose tissue, and liver (Ruderman *et al.*, 2003). Studies with pharmacological inhibitors of AMPK and in animal models harboring AMPK deletions indicate that AMPK activation positively regulates glucose uptake and metabolism. The serum glucose lowering effects of LKB-AMPK pathway activation occurs through CREB-dependent transcription of PGC- α and subsequent inhibition of the glucogenic enzymes, phosphoenolpyruvate carboxykinase and glucose-6-phosphatase (Koo *et al.*, 2005).

In addition to its role in glucose metabolism, the LKB1-AMPK pathway plays a critical role in the regulation of fatty acid oxidation in skeletal muscle and liver. AMPK increases fatty acid oxidation by phosphorylating the inhibitory site of acetyl-CoA-carboxylase, one of the main rate-controlling enzymes for the synthesis of malonyl-CoA, a potent inhibitor

of mitochondrial fatty acid oxidation. AMPK also represses pyruvate kinase and fatty acid synthase expression leading to decreased lipogenesis (Cook and Gamble, 1987; Leclerc *et al.*, 1998). These actions can contribute to the prevention of obesity and insulin resistance.

Although studies of LKB1-AMPK function in animal models of T2DM indicate that pathway activation may prevent disease onset, data collected to date from individuals with obesity and insulin resistance, with or without diabetes, have not detected aberrant AMPK activity in skeletal muscle of these patients (Hojlund *et al.*, 2004). These studies suggest that impaired insulin action on glycogen synthesis and lipid oxidation in skeletal muscle of these patients is not associated with altered AMPK expression or activity. However, it has also been reported that exercise-induced activation of AMPK is impaired in muscle of obese individuals with or without T2DM suggesting that activation above basal level could be effective in the treatment of diabetes and metabolic syndromes (Steinberg *et al.*, 2004).

FYN tyrosine kinase as a novel regulator of LKB1/AMPK

Recently, FYN, a non-RTK of the SRC family, was shown to play a role in insulin sensitivity and lipid utilization by regulating LKB1 function (Figure 3(b)). FYN knockout mice exhibit marked reductions in adiposity, fasting glucose and insulin levels, as well as improved insulin sensitivity (Bastie *et al.*, 2007). FYN deletion also improved plasma and tissue triglycerides, increased energy expenditure and enhanced fatty acid oxidation. The increased catabolism coincided with increased mitochondrial markers and AMPK phosphorylation in adipose tissue and skeletal muscle. Pharmacological inhibition of FYN in wild type mice induces weight loss, due to increased fatty acid oxidation associated with whole-body energy expenditure. FYN was also shown to modulate LKB1 subcellular localization through direct phosphorylation of LKB1 tyrosines 261 and 365. Mutation of these residues within LKB1 results in cytoplasmic localization and subsequent activation of AMPK1 in muscle cells (Yamada *et al.*, 2010). These findings establish the proto-oncogene FYN as a novel nutrient sensor and regulator of adipose tissue mass and insulin sensitivity. Taken together these observations indicate that activation of oncogenic signaling pathways through mutations in oncogenes or loss of tumor suppressors can impair or improve metabolic control.

Introduction

Interest in the cell cycle dates all the way back to the mid-nineteenth century and the work of Walther Flemming, one of the founding fathers of microbiology. One of Flemming's most lasting contributions to science was his innovative use of aniline dyes, which allow the visualization of structures inside cells, especially the DNA of eukaryotes. Once it became possible to see chromatin and chromosomes, two terms coined by Flemming, the events of mitosis were first observed. Because these were the most visually conspicuous activities that were observable to early microbiologists, attention quickly focused on them and Flemming (1882) became the first biologist to study the cell cycle (Figure 1).

By observing and describing the events of mitosis, another term he coined, Flemming was the first to suggest that new cells get their nuclei from the division of the nucleus of the parent cell. This claim heavily influenced the development of modern cell theory, which states that all cells come from the division of a preexisting cell.

It was not until Morgan (1919) confirmed the role of chromosomes in conveying genetic information did biologists begin to understand the purpose and function of mitosis. By this time, the work of Mendel was being rediscovered, and the modern evolutionary synthesis was joining molecular biology with field biology under the grand unifying theme of evolution by natural selection. The central role of meiosis and mitosis in the propagation of genetic material through the ages thenceforth became clear.

The Discovery of Regulators of the Cell Cycle

After mitosis, the next phase of the cell cycle to be discovered was S phase, the DNA synthesis phase when chromosomes are

duplicated (Swift, 1950). However, it was noted that, in eukaryotes, DNA synthesis does not happen right before mitosis, as might be predicted. Instead, the synthesis of DNA occurs in a discrete, predictable, and relatively short period of time distinct from the events of mitosis. The period of time from the birth of a new cell until it begins synthesizing new DNA was named the first 'gap phase,' later shortened to G₁. The period of time after the completion of DNA synthesis and before the beginning of mitosis was called the second gap phase, or G₂. These two gap phases comprise the large majority of time in a given cell cycle, even in a cell population that is dividing as rapidly as it can. (Exceptions to this rule are found during embryogenesis and the development of multinucleate tissues such as skeletal muscle and fungal hyphae.) For an extensive review of the history of cell cycle research, see (Nurse, 2000; Figure 2).

Research into the cell cycle entered the modern era with the work of Tim Hunt using sea urchin eggs in 1982 (Evans *et al.*, 1983). Not coincidentally, sea urchin eggs were also the model system in which meiosis had been discovered a century earlier. It had previously been shown that protein synthesis inhibitors will almost immediately halt the growth and division of sea urchin embryos, even though these embryos are not engaging in a large amount of protein synthesis during the first several rounds of cell division. In all dueterostomes, the first phase of embryonic development, cleavage, is marked by rapid cycling through S phase, M phase, and cytokinesis, skipping the gap phases and with little or no growth in the overall size of the embryo. The result is a 128-cell embryo that is the same size as the original unfertilized egg.

That protein synthesis is required for cleavage to continue, even though little or no growth is taking place, suggested that a specific protein or proteins are required for cells to proceed through the cell cycle. This is what Tim Hunt was searching for in the summer of 1982. Sure enough, using radioactive pulse-chase experiments, he observed a protein that appeared and disappeared in a regular cyclic pattern that corresponded to the

Figure 1 Drawing by Walther Flemming of a cell from the salivary gland of a chironomid larva, showing the polytene chromosomes.

Figure 2 The phases of the eukaryotic cell cycle.

timing of the divisions of the sea urchin embryos. Specifically, the band disappeared rather suddenly about 10 minutes before the cells began the visible process of division (cytokinesis). Hunt (2004) named this protein cyclin in homage to his favorite hobby, cycling. The name stuck, given the obvious connection to the cycling of growing cells.

The cyclin that Hunt first observed was almost certainly what is now known as cyclin A (Evans *et al.*, 1983). Cyclins were subsequently observed in a variety of organisms. While cyclin A tends to gradually accumulate as a cell grows and then suddenly disappears as it prepares to divide, other cyclins have different patterns through the cell cycle.

Hunt's work on cyclins soon joined with work done by Paul Nurse and colleagues on *cdc2* (Nurse and Bissett, 1981) and that of Marc Kirschner and colleagues on the Maturation Promoting Factor, MPF (Cyert and Kirschner, 1988). It was eventually realized that cyclins are regulatory components of larger multi-protein enzyme complexes. The catalytic part of the complex, first discovered by Nurse as *cdc2p* in fission yeast (*cdc28p* in budding yeast), is a kinase that requires association with the cyclin to become active. Human *cdc2* was then re-named cyclin-dependent kinase 1 (CDKs), the founding member of the CDK family (Figure 2).

The Cyclins

Cyclins are found in every cell throughout all eukaryotes. Given the long history and frequent gene duplication, the cyclin family is quite large, with 30 identified members to date. Different cyclins function in different phases of the cell cycle in concert with their associated CDK, and different subtypes show specific tissue-distribution patterns in multicellular organisms. Nevertheless, the proteins are highly conserved, as evidenced by the fact that human cyclins can substitute for yeast cyclins to form functional cyclin-CDK complexes (Lew *et al.*, 1991).

Cyclin A, the founding member of the cyclin family of proteins, begins to accumulate in cells in late G1 phase, peaks in mid-G2 phase, and disappears completely at the beginning of mitosis (Sherr, 1994). In mammals, two genes encode slightly different forms of cyclin A: *CCNA1*, or cyclin A1, which is expressed almost exclusively in germ cells and *CCNA2*, or cyclin A2, which is expressed ubiquitously. Cyclin A partners with CDK2 in late G1 and S phases and with CDK1(*cdc2*) in late S and G2 phase (Pagano *et al.*, 1992). As is true for most all cyclins, the association of cyclin A with its partner CDKs induces a conformational change in the kinases to allow catalytic activity and to help direct substrate preference.

Other cyclins show a different pattern of cell cycle expression and complex with different CDKs. For example, D-type cyclins are present throughout the cell cycle in cells that are actively dividing and disappear only when cells exit the cell cycle temporarily during quiescence or permanently during senescence (Sherr, 1993). E-type cyclins, on the other hand, are expressed during a narrow window of time from mid-G1 to mid-S phase (Dulic *et al.*, 1992). B-type cyclins, also called the mitotic cyclins, only appreciably accumulate in G2 phase, reaching their peak in mid-mitosis before suddenly disappearing before cytokinesis (Fung and Poon, 2005).

Key to the mechanism of how cyclins execute cell cycle control is their carefully timed and sequential accumulation and degradation (Koepp *et al.*, 1999). Although transcriptional activation/repression plays a role, the greater part of this tight temporal control of protein expression is achieved through regulation of the stability of the cyclin proteins. Cyclins are markedly unstable proteins, often exhibiting a turnover rate that is among the highest of any known class of proteins. Accumulation is only achieved through the temporary stabilization of the proteins, an effect which is easily reversible, and the mechanism of which is particular to each cyclin. Thus, it should come as no surprise that a great deal of groundbreaking work on ubiquitin-mediated proteolysis was conducted while studying the very rapid and tightly regulated destruction of yeast cyclins during the cell cycle (Bai *et al.*, 1996).

At the same time, many cyclins have functions entirely separate from the cell cycle. For example, although cyclin C shares substantial sequence identity with the other cyclins and was identified in the same screen that identified cyclins D and E, it does not fluctuate through the cell cycle. Instead, cyclin C forms a complex with CDK8, which then phosphorylates the C-terminus of RNA polymerase II, a key event for transcriptional initiation (Rickert *et al.*, 1996). Similarly, cyclin H, together with CDK7 and another protein, MAT1, form a ternary complex that is an essential part of TFIID, a central component of the basal transcription machinery (Shiekhattar *et al.*, 1995). Although cyclin H-CDK7-MAT1 may also have a role in activating other CDKs, it appears constitutively active through the cycle and in quiescent cells.

Because not all cyclins fluctuate in the cell cycle, nor do all seem to bind to a CDK partner, the recognition and naming of members of the cyclin superfamily is now based on sequence similarity. The characteristic structure of a cyclin is found in the cyclin box, a large domain of about 100 amino acids that forms a characteristic folding of five alpha-helices (Noble *et al.*, 1997). All cyclins have one or two cyclin boxes, but the domain is found in other proteins as well, such as pRb and TFIIB. The cyclin box is key to the two most important features of the cyclins with respect to cell cycle control: binding to CDKs and the rapid turnover of cyclins by ubiquitin-mediated proteolysis. Table 1 below lists the cyclins known to date.

The Cyclin-Dependent Kinases

The cyclins do not have enzymatic activity. Instead, they appear to exert their function through altering the activity, localization, stability, and substrate preference of their catalytic binding partners, the cyclin-dependent kinases (CDKs) (Moragan, 1997). Accordingly, yeast cells have only one CDK: *cdc2p* in the fission yeast *Schizosaccharomyces pombe*, and *cdc28p* in the budding yeast *Saccharomyces cerevisiae*. The diversity of functions borne by the sole CDK is achieved by the sequential accumulation and degradation of various cyclins. For example, in budding yeast, the G1 cyclin Cln3p binds to and activates *cdc28p* to mediate G1 phase progression. The actions of Cln3p-*cdc28p* lead to accumulation of the next cyclins, Cln1 and Cln2. These cyclins replace Cln3 in the complex with *cdc28p* and direct it toward new targets then lead to the accumulation of the S-phase cyclins, Clb5 and Clb6. The targets

Table 1 The cyclin superfamily of proteins

Cyclin family	Genes	CDK partner	Other binding partners	Known roles
A	CCNA1, CCNA2	CDK1, CDK2	CDC6	S-G2 transition, G2 phase progression (Pagano <i>et al.</i> , 1992)
B	CCNB1, CCNB2, CCNB3	CDK1	TGFB2	M phase entry and exit (Hayles <i>et al.</i> , 1994)
C	CCNC	CDK8	MED proteins	Transcriptional initiation (Rickert <i>et al.</i> , 1996)
D	CCND1, CCND2, CCND3	CDK4, CDK6	p21, p16INK4a	Phosphorylation of pRb, G1 progression (Matsushime <i>et al.</i> , 1994)
E	CCNE1, CCNE2	CDK2	p21, p27	Phosphorylation of pRb, G1-S phase transition (Koff <i>et al.</i> , 1992)
F	CCNF	None	SKP1, CUL1, CP110	G2-M transition (Kong <i>et al.</i> , 2000)
G	CCNG1, CCNG2	None	p16INK4a, Mdm2, p53	Unknown
H	CCNH	CDK7	MAT1	TFIIH function (Feaver <i>et al.</i> , 1994), CDK-activating kinase (Makela <i>et al.</i> , 1994)
I	CCNI1, CCNI2	CDK5	Unknown	Differentiation/anti-apoptosis (Griffin <i>et al.</i> , 2006)
J	CCNJ, CCNJL	Unknown	Unknown	Unknown
K	CCNK	CDK9, 12, 13	RNA pol II	Transcriptional elongation (Edwards <i>et al.</i> , 1998)
L	CCNL1, CCNL2	CDK11	Unknown	mRNA splicing (Dickinson <i>et al.</i> , 2002)
M	FAM58A, FAM58B	CDK10	Unknown	Development, apoptosis (Guen <i>et al.</i> , 2013)
O	CCNO	Unknown	Unknown	Unknown
T	CCNT1, CCNT2	CDK9	RNA pol II	Transcriptional elongation (Peng <i>et al.</i> , 1998)
Y	CCNY, CCNYL1, CCNYL2	CDK14, CDK16	LRP6	Wnt signaling (Jiang <i>et al.</i> , 2009)

and functions of the same CDK, cdc28p, change throughout the cell cycle based on which cyclin is bound to it. For a review of yeast cyclins and CDKs, see Mendenhall and Hodge (1998).

The situation in metazoans is similar, but much more complicated. The prototypical CDK, CDK1 (previously known as cdc2 from its initial discovery as the human homolog of the *S. pombe* gene of the same name) is accompanied by more than 20 other CDKs, not all of which function in the cell cycle. In general, the protein levels of the CDKs do not fluctuate through the cell cycle as much as do the cyclins, though they do accumulate to moderately higher levels in the phases in which they are most enzymatically active. While most cyclins are medium-sized proteins at 50–60 kDa, the CDKs are substantially smaller at 30–40 kDa, underscoring the notion that the cyclins are the regulatory nodes of the enzyme complexes and the CDKs are the catalytic component.

There are more than 20 members of the CDK family in humans. Like the cyclins, the CDKs are highly conserved in eukaryotes. Human CDK1 shares more 60% sequence identity with the yeast cdc28p. Also like the cyclins, discoveries of non-cyclin-dependent and non-cell cycle-related functions have led to a structure-based definition of the CDK family of proteins (Malumbres *et al.*, 2009). To that end, the PSTAIRE helix (named for the conserved amino acids), which can also take the form PFTAIRE and other variations thereof, has been proposed as the family-defining feature of the CDKs (Table 2).

While the cyclins are larger and display a great deal of structural diversity, most CDKs are relatively compact proteins and have much less divergent structures among them. The majority of their structure is devoted to the formation of the kinase domain and only a few regulatory motifs are present.

Near the N-terminus, the CDKs contain an ATP-binding pocket, conserved among all kinase proteins, which includes one or two phospho-regulatory sites that usually inactivate the kinase when phosphorylated (Pavletich, 1999). In the C-terminal half of the protein is a characteristic T-loop structure that contains both the cyclin-binding domain (PSTAIRE box) and another phospho-regulatory threonine residue. In contrast, phosphorylation within the T-loop is required for enzymatic activity. Phosphorylation of the T-loop, together with cyclin binding, swings open the T-loop, making the active site accessible. The CDKs are proline-driven serine/threonine kinases and the consensus protein sequence for substrate recognition is S/T-P-X-K/R, although variations have been noted (Endicott *et al.*, 1999; Figure 3).

Functions of Cyclin-CDK in the Cell Cycle and Quiescence

Perhaps the most understood function of cyclins and CDKs is their control of cell cycle progression. Cyclin-CDK complexes appear to be the ‘master regulators’ of the cell cycle, controlling the events and timing that define each phase (Figure 4).

Cell cycle control begins with the D-type cyclins (Sherr, 1994). Cells that have temporarily exited the cell cycle and are not dividing are said to be quiescent, a state often referred to as G0 phase. While CDKs may be present in quiescent cells, they are not active because the cell cycle-related cyclins are not detectable. However, when cells are stimulated to reenter the cell cycle and begin dividing, either through addition of a growth factor or loss of contact inhibition, the D-type cyclins

Table 2 The cyclin-dependent kinase superfamily of proteins

CDK	Other names	Cyclin(s)	Major target(s)	Known roles
CDK1	CDC2, CDC28A, CDKN1	A, B	pRb family, MCM family, ORC1, APC, FOXM1, FOXO1	G2 progression, initiation of mitosis (Draetta and Beach, 1988)
CDK2	CDKN2	A, E	pRb family, MCM family, NPM, MYC, NPAT	G1 and S-phase progression (Koff <i>et al.</i> , 1992)
CDK3	CDKN3	C	ATF1	Transcriptional initiation (Zheng <i>et al.</i> , 2008)
CDK4	NCLK, PSSALRE	D	pRb family	G1 progression (Kato <i>et al.</i> , 1993)
CDK5		–		Neuronal signaling and development (Nikolic <i>et al.</i> , 1996)
CDK6	PLSTIRE	D	pRb family	G1 progression (Meyerson and Harlow, 1994)
CDK7	MO15	H	RNA pol II, T-loop of CDKs	TFIIH function (Roy <i>et al.</i> , 1994), CDK-activating kinase (Solomon <i>et al.</i> , 1993)
CDK8		C	RNA pol II, cyclin H	Transcriptional initiation (Rickert <i>et al.</i> , 1996)
CDK9	P-TEFb, PITALRE, CDC2L4, TAK	T, K	RNA pol II	Transcriptional elongation (Wei <i>et al.</i> , 1998)
CDK10	PISSLRE	M	ETS2	Cell growth in development, apoptosis (Kasten and Giordano, 2001)
CDK11	PITSLRE, PITSVRE	L	Unknown	Apoptosis, formation of RNA pol II L-mediator complex (Hu <i>et al.</i> , 2003)
CDK12	CRK7	K	RNA pol II, SRSF1/SF2	Transcriptional elongation (Bartkowiak <i>et al.</i> , 2010), RNA splicing (Chen <i>et al.</i> , 2006)
CDK13	CDC2L, CDC2L5, CHED	K	RNA pol II, SRSF1/SF2	Transcriptional elongation, RNA splicing (Chen <i>et al.</i> , 2007)
CDK14	PFTK1, PFTAIRES1	Y	LRP6	Wnt signaling (Davidson <i>et al.</i> , 2009)
CDK15	PFTAIRES2	Unknown	Unknown	Unknown
CDK16	PCTAIRES1, PCTK1	Y	NSF	Neural vesicle transport and exocytosis, neurite outgrowth (Graeser <i>et al.</i> , 2002)
CDK17	PCTAIRES2, PCTK2	Unknown	Unknown	Neuronal differentiation (Hirose <i>et al.</i> , 1997)
CDK18	PCTAIRES3, PCTK3	Unknown	Unknown	Unknown
CDK19	CDC2L6	Unknown	Unknown	Formation of mediator complex of RNA pol II (Ender <i>et al.</i> , 2008)
CDK20	PNQALRE, CCRK, CAK-kinase-p42	None	CDKs	Shh signaling, Cilia formation (Ko <i>et al.</i> , 2010)

(Cln3 in yeast) begin to accumulate in 2–3 h. In mammals, the D cyclins then bind to and activate CDK4 and/or CDK6. The only bona fide catalytic targets of D-cyclin complexes are the three pocket proteins: the retinoblastoma protein, pRb (RB1); p107 (RBL1); and p130 (RBL2) (Weinberg, 1995). Unlike that of other cell cycle cyclins, the levels of D-type cyclins remains high through the cell cycle, as long as the cells are stimulated and actively progressing through the cycle. Only upon withdrawal of growth factor, contact inhibition, or other anti-mitogenic signaling do the D-type cyclins disappear (Won *et al.*, 1992).

The initial phosphorylation of pocket proteins by cyclin D-CDKs in early G1 phase results in a conformational change that allows its binding partner, E2F, to become partially active. This event, which typically takes 3–5 h to be detectable, marks the progression of cells into mid-G1 phase. E2F is a transcription factor that trans-activates many cell cycle-related genes. The net effect of D-cyclin activity on E2F is to allow the

expression of the next G1 phase cyclin: cyclin E (Harbour and Dean, 2000; Ohtani *et al.*, 1995).

E cyclins then complex with CDK2 (in mammalian cells). The Cyclin E-CDK2 complex has several known targets for its kinase activity, which can be collectively understood as preparation for S-phase entry. For example, E-CDK2 phosphorylates nucleophosmin and CP110, triggering centrosome duplication (Chen *et al.*, 2002; Okuda *et al.*, 2000). E-CDK2 also activates p220(NPAT), which promotes transcription of the histone genes, in preparation for chromosome duplication (Zhao *et al.*, 2000). Finally, and perhaps most importantly, E-CDK2 continues the phosphorylation of pRb and the other pocket proteins that was previously begun by D-CDK4/6 (Harbour *et al.*, 1999). The hyper-phosphorylation of pRb completes its inactivation, fully releasing E2F to transcribe many S-phase genes such as DNA polymerase α , thymidine kinase, dihydrofolate reductase, and the next cyclin, cyclin A (Ren *et al.*, 2002). A final function of cyclin E is to promote the

Figure 3 The major activating steps of the MPF complex.

Figure 4 Associations and modifications regulating cyclin-CDK activity.

assembly of the pre-replication complex (Coverley *et al.*, 2002). Thus, the activity of E-CDK2 typically marks the transition from G1 phase into S-phase. By mid-S phase, levels of cyclin E drop dramatically (Figure 5).

The A-type cyclins begin to appear in late G1 and build throughout S phase. Initially, they bind to CDK2, replacing cyclin E after S phase has begun. Temporally speaking, the first function of A-CDK2 is to phosphorylate the ORC (origin recognition complex) and MCM (mini-chromosome maintenance) proteins in order to allow firing of replication origins (Lei and Tye, 2001). This begins DNA synthesis. Soon after, A-CDK2 then phosphorylates cdc6, which promotes disassembly of the ORC complexes (Petersen *et al.*, 1999). This second function of A-CDK2 ensures that each origin fires once and only once.

As cells complete DNA replication and begin G2 phase, cyclin A begins to join with CDK1, although A-CDK2

complexes persist into mitosis and likely play a role in spindle formation (Pagano *et al.*, 1992). A-CDK1 complexes, on the other hand, are active for a narrow window between mid-S phase and late G2 phase. A-CDK1 appears to have roles analogous to A-CDK2 in preventing multiple firing of replication origins, an important consideration given that re-replication of DNA can lead to genomic catastrophe and neoplasia. G2 functions of A-CDK1 are the execution of checkpoint controls, discussed below.

Levels of cyclin B build more slowly than the other cyclins, beginning in late G1 and only reaching appreciable levels in mid-G2, when it begins to replace cyclin A in complexes with CDK1. The cyclin C-CDK1 complex is also known as maturation promoting factor (MPF), which begins to form well before it comes enzymatically active (Murray *et al.*, 1989). The final activating step, which takes place in late G2 is the

Figure 5 Timing of cyclin accumulation through the mammalian cell cycle.

removal of an inhibitory phosphorylation by the phosphatase Cdc25 (Gu *et al.*, 1992). Once active, MPF induces chromosome condensation via phosphorylation of condensin, dissolution of the nuclear lamina via phosphorylation of the lamin proteins, fragmentation of the organelles of the endomembrane system through phosphorylation of GM130, and the formation of the mitotic spindle through several targets. Cyclin B levels, and MPF activity, peaks at the moment mitosis begins, after which cyclin B is degraded to undetectable levels rather quickly. Cyclin B is targeted for degradation by the Anaphase Promoting Complex, an E3 ubiquitin ligase (Peters, 2002). Only when cyclin B is degraded do the sister chromatids separate and begin migrating to opposite centrosomes. The remaining steps of mitosis occur without regulation by cyclin-CDK complexes.

CKIs: CDK Inhibitors

Regulation of cyclin-CDK activity is multilayered. Besides cyclin binding, the kinase activity of CDKs is affected by both inhibitory and activating phosphorylation, discussed above. In addition, there are several small proteins that act as inhibitors to cyclin-CDK complexes called CKIs, cyclin-dependent kinase inhibitors (Sherr and Roberts, 1999). These small proteins lack extensive secondary or tertiary structure and instead act merely to disable kinase activity through various mechanisms.

There are two families of CKIs, the INK4 proteins and the CIP/KIP proteins. The INK4 proteins were so-named for their ability to inhibit CDK4. (They similarly inhibit the CDK4 analog CDK6.) These proteins bind to CDK4/6 in a manner that is directly competitive with the D-cyclins. By doing so, they prevent activation of CDK4/6 kinase activity and subsequent phosphorylation of the pRb family of pocket proteins (Hengst *et al.*, 1994). Without the action of D-cyclin kinase activity, the pocket proteins accumulate in their un- and under-phosphorylated forms, which then repress the E2F transcription factors. As such, the INK4 proteins are effective at halting cell cycle progression and will be discussed below for their role as tumor suppressors.

The CIP/KIP proteins function more broadly as CKIs, capable of inhibiting all or nearly all of the cyclin-CDK complexes that function in cell cycle regulation (Sherr and Roberts, 1999). In addition, their function is more nuanced. CIP/KIP

Table 3 The CDK inhibitors (CKIs)

CKI type	Member (gene name)	CDKs inhibited
INK4	p16Ink4A (CDKN2A) p15INK4B (CDKN2B) p18INK4C (CDKN2C) p19INK4D (CDKN2D)	CDK4, CDK6
CIP/KIP	p21CIP1/WAF1 (CDKN1A) p27KIP1 (CDKN1B) p57KIP2 (CDKN1C)	All cell cycle-related CDKs

proteins bind both to the cyclins and the CDKs and, when present in high concentration, can disrupt and/or inhibit these proteins even after they have formed. However, at lower concentrations, the CIP/KIP proteins may actually promote D-, E-, and possibly A- cyclin-CDK activity, either through a role in recruitment/complex formation, or nuclear translocation. Nevertheless, the CIP/KIP proteins, through their inhibition of cyclin-CDK complexes, can also put the breaks on cell cycle progression and thus function as tumor suppressors (Table 3).

Cyclins, CDKs, and CKIs in Cancer

Mutations of Cyclins and CDKs in Cancer

Given their role in promoting cell growth and division, it is not surprising that a great deal of attention has been paid to the role of the cyclins and CDKs in the genesis of cancer. However, CDK and cyclin genes are not common targets of mutation in cancer. Of all the CDK genes, only *CDK4* has been reported as a mutated oncogene and only in a single type of cancer, melanoma, in less than 5% of cases (Goldstein *et al.*, 2000). This is not altogether surprising given that full activation of the CDKs requires several regulatory steps and cannot be achieved through overexpression or mutation alone. Perhaps more surprising is that neither are the cyclins frequent targets of gene mutation in cancer, other than through gene duplication. Exceptions are that *CCND1* gene amplifications are occasionally found in a variety of cancers including that of breast, uterine, colon, and the head, while mutations in cyclin E1 sometimes appear in hepatocellular carcinoma. In both cases, mutations or duplications in cyclin genes seem to be the

result of the advanced progression of cancer, not its initiation (Sherr and McCormick, 2002).

Overexpression of Cyclins in Cancer

More commonly, however, the D-, E-, and A-cyclins are observed to be overexpressed in human cancers, owing at least in part to the fact that the most common proto-oncogenes (K-RAS, MYC, BCR-ABL, HER-2/neu, C-KIT, EGFR, B-Raf) all induce the expression of the cyclins as part of their common mechanism of action (Croce, 2008). The vast majority of proto-oncogenes encode proteins that operate in the normal extracellular signaling pathways that promote cell growth and proliferation. As such, they sit directly upstream of the cyclins in their mechanism of action. There is an advantage for cancer to activate genes that act upstream in the mitogenic signaling cascade, rather than downstream, because the latter form of misregulation is often sensed as unscheduled cell division, which trips the anti-proliferative defense mechanisms of apoptosis or senescence. Mutations in growth factor receptors, however, often promote both cell division and survival, making them much more powerful than a cyclin mutation in the genesis of neoplasia.

Because cancer cells proliferate faster than normal cells and subvert cues to restrain their growth, the cyclins and CDKs are typically overexpressed or overactive in these cells. Because cyclin-CDK complexes are the vehicles of, and rate-limiting factors in, cell proliferation, they are attractive targets for cancer treatments. To date, no CDK inhibitors have begun human trials as anticancer drugs, despite years of research thereof. Although the FDA has recently approved an inhibitor of CDK4/6 for human trials (Brower, 2014), this has come nearly three decades after the discovery of CDKs and after similar inhibitors of CDK1 and CDK2 have failed miserably in animal trials. Presumably, this owes to the extreme toxicity of these drugs, given that specificity toward specific CDKs or even just to CDKs over other kinases, has been elusive. No pharmaceuticals have yet been reported that are able to specifically disrupt the function of cyclins, though attempts to do so with miRNAs and monoclonal antibodies are ongoing. In contrast, some inhibitors of tyrosine kinase receptors have been in the pharmacopeia of cancer treatment for nearly two decades.

The CKIs: Bona Fide Tumor Suppressors

Cyclin-dependent kinase inhibitors (CKIs), on the other hand, are very frequently mutated in human cancers. This is because the natural function of CKIs is to halt or slow cellular proliferation. These genes are thus referred to as tumor suppressors, a label that is borne out by mouse models demonstrating that loss of the CKIs accelerates tumorigenesis dramatically.

INK4a is one of the most frequently mutated human tumor suppressor genes, with deletions and mutations having been reported in a wide variety of human cancers. In addition, epigenetic silencing of the locus has also been reported, usually through DNA methylation. Interpretation of mutations and gene silencing is complicated by the fact that a different tumor suppressor, p19ARF, is also encoded by the *CDKN2A* locus in an alternate reading frame (Sherr, 2001). Two distinct

tumor suppressors, indeed two of the most important tumor suppressors in our defense against cancer, are collocated within the same stretch of DNA, meaning that a single deletion or mutation event could disrupt both gene products. This is a remarkable evolutionary conundrum, given that a simple gene duplication event with subsequent divergence of the two loci would solve this genetic hyper-vulnerability.

The CIP/KIP proteins are also bona fide tumor suppressors as their deletion in mice lead to increased development of malignancy (Denicourt and Dowdy, 2004). Even more dramatically, loss or mutation of CIP/KIP genes exacerbates tumorigenesis in other cancer-prone genetic backgrounds. This argues that CKIs function as key operators in the cancer protective mechanisms of other tumor suppressors. Indeed, discovery of p21CIP1/WAF1 was announced in back-to-back papers, one describing its ability to suppress the activities of the CDKs and one describing it as a primary means by which the p53 'master tumor suppressor' mediates cell cycle arrest (Harper *et al.*, 1993; El-Deiry *et al.*, 1993). Nevertheless, loss-of-function mutations in the *CDKN1* loci are not common in human cancers, as they are with other tumor suppressor genes such as *RB1* and *TP53*. Indeed, CIP/KIP proteins are frequently observed to be overexpressed in human tumors and correlate with poor prognosis. Although oncogenic roles for these CKIs have been postulated, in many cases, this overexpression is likely the result of a failed attempt by damaged cells to contain their own malignancy.

Although the cyclins, CDKs, and CKIs are not among the list of the most frequently mutated or deleted proto-oncogenes or tumor suppressors, they are intimately connected with all those that are, as effectors, activators, or inhibitors. Neither tumor suppression nor tumorigenesis can occur without the direct involvement of the cyclins and CDKs. Cancer is a disease of the cell cycle.

Beyond the Cell Cycle: Other Functions of Cyclins and CDKs

In addition to their most famous role in cell cycle regulation, the cyclins and CDKs are being linked to an ever-increasing number of non-cell cycle-related functions. In mammals, this is likely the result of frequent gene duplication and redundancy among cyclins and CDKs, which has allowed new functions to emerge. The levels of some cyclins and most CDKs do not fluctuate appreciably through the various phases of the cell cycle, being impervious even to cell cycle exit. In the early 2000s, the cancer biology community was shocked to learn that many cyclins and CDKs were genetically dispensable in mice, presumably due to compensation and substitution by other family members (Satyanarayana and Kaldis, 2009). However, mice lacking individual cyclins or CDKs often have unexpected specific phenotypes unrelated to cellular proliferation, revealing novel functions of these gene products.

The connection between the cell cycle and transcription runs deep. Although many of the cell cycle roles of the cyclin-CDKs are executed through the phosphorylation of transcriptional activators or repressors, many cyclins and CDKs also function within the basal transcription machinery itself. Most often, cyclin-CDK complexes act to phosphorylate the C-terminal domain (CTD) of RNA polymerase II in a

sequential fashion, leading to the progressive recruitment of the basal machinery, transcriptional initiation, and elongation (Dymlach, 1997). The sequential phosphorylation of the CTD by cyclin-CDK is highly reminiscent of the sequential phosphorylation of the pocket proteins (or vice versa). Roles for cyclin-CDKs in pre-mRNA splicing have also been discovered.

Even more surprising are the discoveries that cyclins and CDKs may have functions that do not require association with a respective partner. For example, CDK10 is known to bind directly to the transcription factor ETS2 in the absence of a cyclin partner (Kasten and Giordano, 2001). Its repression of ETS2-mediated transcription of proto-oncogenic *RAF1*, which requires no kinase activity, can even promote tumorigenicity despite CDK10 itself being regulated wholly separate from the cell cycle. CDK5 has long been an outlier of the CDK family in that it seems to function only in terminally differentiated neuronal cells and does so entirely without the assistance of a cyclin partner (Dhavan and Tsai, 2001). Further, cyclins, CDKs, and even CKIs have been shown to operate in DNA damage checkpoints and repair mechanisms in an entirely cell cycle-independent manner.

More recently, the cyclins and CDKs are popping up in the study of differentiation, cell fate determination, and cell cycle exit as well as tissue renewal, stem cell proliferation, and meiosis (Lim and Kaldis, 2013). Importantly, the newly discovered roles for cyclin-CDKs in these proliferative and anti-proliferative processes are not always tied directly to cell cycle progression. Highly tissue- and context-specific functions are being discovered for the less studied cyclins and CDKs, as are new roles for the well known ones via new effectors. While it is tempting to interpret these roles as purely a function of cell cycle regulation, it does not appear to be so.

The summary of this is that the cyclin-CDK complex has formed a modular unit that has proven highly useful for eukaryotic cells. Cyclin-CDK units can be regulated by a variety of overlapping mechanisms such as complex assembly, the binding of a CKI, subcellular localization, protein stability, and posttranslational modification. In particular, the labile nature of the cyclin protein lends itself to exquisite temporal regulation. Furthermore, substrate and effector preferences of the cyclin-CDK pair are malleable and can be altered by protein-protein interactions. As such, through gene duplication events, the course of evolutionary time has seen the proliferation of these complexes and their subsequent adaptation for a variety of cellular uses. From the cellular proliferation of early embryos to the recruitment of stem cells for tissue renewal, cyclin-CDK complexes are the engines that drive, or the brakes that stop, the growth of all eukaryotic cells.

Glossary

Competence A quiescent cell is induced to enter into a state after a brief pulse of growth factors that allows entrance into S phase after a second pulse of growth factors.

DREAM A multi-protein complex that includes DP, RB-related, E2F, and MuvB and plays a direct role in establishing and maintaining the quiescent state.

G1/S The period in G1 after a cell has passed the restriction point but before DNA synthesis begins.

G1/S checkpoint A DNA damage checkpoint induced by activation of p53 and p21.

p53 A major cellular tumor suppressor (TP53) that is involved in many processes including apoptosis, DNA damage response, and cellular senescence.

Quiescence (G0) A viable state when normal cells are cultured without growth factors and remain capable of reentering the cell cycle when growth factors are restored.

RB The product of the retinoblastoma tumor suppressor gene RB1 that regulates E2F dependent gene expression.

RB-related proteins p107 (RBL1) and p130 (RBL2).

Restriction point A point in the G1 phase of the cell cycle when progression into S phase becomes independent of growth factors.

Senescence A viable but permanent state when cells have become committed to entering S phase but are unable due to increased p53, p21, and p16 levels.

Terminal differentiation A viable but permanent state when cells have exited from the cell cycle and display a differentiated phenotype.

The Restriction Point

The mammalian cell cycle is divided into four phases that include mitosis (M), deoxyribonucleic acid (DNA) synthesis (S), G1, and G2. Mitosis is recognized when cells visibly undergo cell division and includes prophase, metaphase, anaphase, and telophase. During S phase, cells duplicate their entire genome by DNA replication. G2 occurs after DNA synthesis has been completed but before chromosomal condensation in mitosis. The G1 phase occurs immediately after mitosis has been completed and before DNA synthesis begins. While the duration of S, G2, and M phases is relatively constant from one cell cycle to the next, there can be large variability in the duration of G1. One of the first observations regarding generation time was that by varying the growth conditions the length of a cell division cycle could change with the duration of G1 responsible for most of this variability. For example, while cells progressed through S, G2, and M phases in relatively invariable time periods, the length of the G1 phase was highly variable and this variability was dependent on the presence of growth factors (Sisken and Morasca, 1965). An important question that this observation raised was whether distinct points within the G1 phase of the cell cycle can be identified.

In 1974, Arthur Pardee published the first report on the restriction point (Pardee, 1974). While a scholar of the American Cancer Society and funded by the NIH, he performed a series of experiments at the Imperial Cancer Research Fund Laboratories in London. It was known that normal cells could be shifted from a proliferative to a quiescent state if serum or nutrients were removed from the culture. Quiescent cells could respond to growth factor addition and begin to proliferate again. However, it was not known whether the quiescent cells had arrested at a distinct point in G1 phase or had they exited from the cell cycle and entered into a new

quiescent phase. To address this question and determine whether distinct points within the G1 phase could be identified, he performed a series of experiments shifting cells from one nutrient deprivation condition to another and observed the length of time it would take for the cells to begin DNA synthesis. He determined that cells starved of serum, amino acids (isoleucine or glutamine), or phosphate or cells cultured at high density were positioned at the same point in the G1 phase relative to S phase. When he shifted cells from one nutrient starved condition to another he found that cells would not enter S phase until complete media was given. Similarly, contact-inhibited cells could not enter S phase if they were re-plated in low serum or amino-deficient media. However, if quiescent or contact-inhibited cells were fed with serum or nutrients for 9 h, they would advance into S phase and into mitosis even after serum or nutrients were removed, revealing a point during G1 when cells no longer needed growth factors to enter S phase. Pardee defined the restriction point for normal cells as a point when they were no longer dependent on nutrients to begin DNA synthesis (Figure 1(a)). He also correctly predicted that cancer cells underwent changes that lost the dependency on growth factors and were not dependent on the restriction point.

The concept that growth factors were required to induce a cell to leave the quiescent state and enter S phase was advanced by demonstrating that distinct growth factors contributed to this ability. Using BALB/c 3T3 cells that were particularly sensitive to contact inhibition, Pledger and colleagues observed that addition of a factor enriched from platelets could induce quiescent cells to advance to a state competent for DNA synthesis (Pledger *et al.*, 1977). In contrast, platelet-poor plasma was not capable of inducing quiescent cells to enter S phase. Platelets provided a growth factor that could induce a state called competence that enabled cells to progress to S phase when fed with platelet-poor plasma.

Figure 1 The G1 phase of the cell cycle. (a) Landmarks of events that occur between mitosis (M) and DNA synthesis (S). When normal cells exit mitosis, they progress through a brief period post mitosis (G1pm) when they are sensitive to growth factors. Absence of growth factors during G1pm results in entry into quiescence known as G0. A brief pulse of growth factors will enable a quiescent cell to move to competence. Addition of growth factors to competent cells enables progression to S phase. The restriction point is reached when cells are no longer dependent on growth factors to enter S phase. The G1ps period extends from quiescence until S phase. The G1/S phase refers to the time in G1 after cells have past the restriction point but before they synthesize DNA. The G1/S checkpoint occurs when cells are fully committed to entering S phase but are unable due to DNA damage signaling. Cells can permanently exit the cell cycle but remain viable by undergoing terminal differentiation or entering into senescence. (b) Factors regulating events during the G1 phase of the cell cycle. The CDK inhibitor p27 is expressed during quiescence and inhibits CDK activity. Un-phosphorylated RB and the DREAM complex repress E2F-dependent gene expression during quiescence. Addition of growth factors to a quiescent cell is necessary to become competent to re-enter the cell cycle. The second addition of growth factors induces cyclin D-CDK4/6 activity that mono-phosphorylates RB, activates PI3K signaling, and represses p53 activity. Cyclin E-CDK2 activity hyper-phosphorylates RB thereby activating E2F-dependent gene expression enabling DNA synthesis. DNA damage can activate p53 and p21 to inhibit CDK2 activity and force entry into the G1/S checkpoint. Cells that repair the DNA damage can reenter the cell cycle. Cells that cannot repair the DNA damage enter into a senescent state with an increase in p53, p21, and p16 levels.

This platelet-derived growth factor was identified as PDGF and shown to be capable of inducing the competent state (Figure 1(a); Pledger *et al.*, 1978). Platelet-poor plasma was capable of advancing competent cells to S phase in a phase called progression (Figure 1(a)). Epidermal growth factor (EGF) and insulin could replace platelet-poor plasma by promoting progression of cells made competent by PDGF. Other labs demonstrated that distinct cell types could use PDGF or other growth factors to induce progression and competence. However, it was noted that not all factors were interchangeable. For most cell types, EGF or insulin was not sufficient to induce a quiescent cell to become competent.

In addition to the decision for a quiescent cell to reenter the cell cycle, it was not known where in G1 would proliferating cells exit the cell cycle when growth factors were removed from the culture. Anders Zetterberg and colleagues used live cell imaging of proliferating Swiss 3T3 cells to determine sensitivity of cellular protein and DNA synthesis after serum withdrawal (Zetterberg and Larsson, 1985). They observed that removal of serum for 1 h at any point within 3 h of completing mitosis significantly extended the time to enter into S phase. They defined this period of sensitivity to serum withdrawal as G1pm (post mitosis) (Figure 1(a)). Notably, EGF or insulin but not PDGF could substitute for serum during the G1pm period indicating that progression but not competence

growth factors could prevent entry into the quiescent state. Once past this point, cells were no longer sensitive to serum withdrawal and could enter into S phase. If growth factors were removed during the G1pm period after mitosis, the cells entered a quiescent state. These quiescent cells could reenter the cell cycle when stimulated with PDGF plus EGF and insulin. However, the length of time for these quiescent or G0 cells to reach S phase was significantly longer than for cells that remained in complete media during the critical G1pm period. The period between quiescence and S phase was termed G1ps (pre-DNA synthesis) (Figure 1(a)). Furthermore, they determined that nearly all of the variability in the length of G1 could be accounted for by the G1ps interval.

The next advance in the restriction point concept was reported in 2001 when it was demonstrated that the requirement for prolonged continuous exposure to growth factors could be replaced with two short intervals of treatments separated by several hours. Although addition of PDGF for 30 min was sufficient to induce a quiescent cell to enter the competent state, the progression growth factors had been added for approximately 7–9 h before reaching the restriction point when growth factors could be removed and continued to S phase. Andrius Kazlauskas and colleagues observed that if quiescent NIH 3T3 or HepG2 cells were treated continuously with PDGF for 10 h, it was sufficient to reach the restriction

point and become committed to the S phase. They analysed how long after these cells were treated with an initial pulse of PDGF did they remain sensitive to addition of a second pulse of PDGF. They observed that cells made competent remained responsive to the second pulse for 8 h and would enter into S phase soon afterwards. If the second pulse was not given for 12 h after the first pulse, S phase entry was delayed for 14 h or as long as it would take if cells had been continuously treated (Jones and Kazlauskas, 2001). They also confirmed the studies of Pledger and colleagues that BALB/c 3T3 cells required PDGF treatment during the first pulse but required EGF or insulin for the second pulse. Furthermore, they confirmed that an initial single pulse with both competence and progression factors were insufficient to induce DNA synthesis. They noted that combined treatment with competence (PDGF) and progression (insulin) factors reduced the time to enter the S phase only by the time lag in the interval between the first and second pulse. They concluded that the competent state was rapidly induced by the initial treatment with competence factors but that it took several hours for competent cells to become responsive to the second pulse of progression factors.

At the same time these studies on the restriction point were taking place, many important discoveries in the RAS and mitogen-activated protein kinase (MAPK) signaling pathways triggered by PDGF, EGF, and insulin were made. In addition, significant insights were reported on the role of MYC in promoting cell growth and the cyclins and cyclin-dependent kinases (CDK) in enabling cell cycle progression. Kazlauskas and colleagues observed that the initial treatment of PDGF triggered immediate tyrosine phosphorylation of the PDGF receptor beta (PDGFRB) but that it quickly vanished after the initial pulse of PDGF was removed. RAS and MAP kinase signaling was also rapidly activated by PDGF treatment. However, PDGF treatment did not immediately lead to increased levels of MYC and cyclin D1 (CCND1). Instead, MYC and cyclin D were detectable soon after the addition of the second pulse of growth factors (Jones and Kazlauskas, 2001; Figure 1(b)). They observed that activation of MAP kinase signaling was required during the first pulse. Treatment with an MEK inhibitor (PD098059) during the first PDGF pulse inhibited entry into S phase even when the second pulse was given without the MEK inhibitor. However, MEK activation was not sufficient to drive cells into S phase. Expression of a constitutively active form of MEK1 (MAP2K1) was not sufficient to drive growth factor-starved cells into S phase (Jones and Kazlauskas, 2001). Notably, constitutively active MEK1 was capable of inducing cyclin D1 expression and kinase activity (Cheng *et al.*, 1998). This indicates that cyclin D expression was also not sufficient to drive cells from quiescence to S phase. However, overexpression of MYC combined with activated MEK1 could induce serum-starved cells to enter S phase.

The Kazlauskas group also explored the signaling events that occurred after the second pulse of growth factors. They determined that introduction of synthetic phosphatidylinositol 3-kinase (PI3K) lipid products could substitute for the second PDGF pulse but not the first. Therefore, the competent state induced by the first pulse of PDGF treatment induced a cellular state sensitive to PI3K signaling (Figure 1(b)). Deciphering the events triggered by the growth factor addition at these two distinct timepoints led to insights into key signaling pathways.

The molecular and signaling events during the two pulses was further explored by the Yarden group (Zwang *et al.*, 2011). Using a clone of normal human mammary epithelial cells, they determined that two 1-hour pulses of EGF given 7 h apart was sufficient to induce serum-starved cells to enter S phase and complete cell division. They observed that while ERK activation occurred immediately after the first and second pulses, the amplitude of the signaling events was much stronger after the second pulse compared to the first pulse. In these cells, the MAPK inhibitor U0126 given during the second pulse could block entry into S phase. In addition, PI3K signaling as evidenced by AKT and S6 phosphorylation was elevated after the second pulse. Inhibition of PI3K and MTOR (mechanistic target of rapamycin) activity with LY294002 during the second pulse could block entry into S phase (Figure 1(b)). This group also performed messenger RNA (mRNA) expression profiling of cells treated with the double pulse protocol. The first pulse induced the gradual and sustained expression of 35 genes involved in lipid biosynthesis that remained elevated until S phase entry. Treatment of cells with an inhibitor of HMG-CoA reductase blocked DNA synthesis indicating that lipid biosynthesis was required during the progression phase. A relatively recent review of the restriction point explores the contributions of biosynthetic events that occur during the progression phase and restriction point in G1 (Foster *et al.*, 2010).

In addition, the second pulse of growth factors specifically down-regulated a second set of genes that were activated by the initial pulse of EGF. Importantly, their down-regulation was dependent on PI3K but not ERK signaling. Among these down-regulated genes was p27 (CDKN1B) or CDK inhibitor. In addition, seven of the ten down-regulated genes were known to be responsive to p53 activation (Zwang *et al.*, 2011; Allen *et al.*, 2014). Importantly, RNAi (RNA interference) knockdown of p53 abrogated the need for the second pulse both in the mammary epithelial cells used as well as in NIH 3T3 cells used by the Kazlauskas lab. These results indicate that MAPK, PI3K, lipid biosynthesis, MYC, p53, and CDK played critical roles in establishing the restriction point (Figure 1(b)). Importantly, they also provided some insight into the events that occurred during progression that enabled a competent cell to be able to pass the restriction point.

In addition to studies of cell lines in culture, there are examples of cells *in vivo* with characteristics of competence that are primed to enter into S phase and proliferate more rapidly in response to a second signal. For example, muscle satellite cells represent the stem cells in adult mice that are capable of regenerating skeletal muscle cells in response to appropriate stimuli. Normally, the satellite stem cells reside in a quiescent state capable of regeneration. They can be induced to enter an activated state by injury to tissue at a distant site through hepatocyte growth factor (HGF) signaling to the MET receptor tyrosine kinase (Rodgers *et al.*, 2014). The activated stem cells were much more likely to enter S phase than quiescent stem cells and also entered S phase much more rapidly. Furthermore, these activated stem cells were larger and had significantly increased ATP levels and mitochondrial activity than quiescent stem cells consistent with elevated PI3K and MTOR activity. Thus, these activated stem cells appeared to have activated PI3K signaling *in vivo* similar to competent cells *in vitro*.

The various studies that explored the restriction point were initially focused on identifying landmarks within the G1 phase of the cell cycle that could account for the requirement for growth factors to advance a normal cell into S phase. In the 40 years that have passed since the initial description of the restriction point, many important insights revealed the signaling events that contribute to proliferation and growth. In addition to the key contributions of signaling by MAPK, PI3K, and MYC to enable cell growth, it also became clear that there were restraining activities that could inhibit cell cycle entry and progression.

The Role of RB and p53 in Establishing the Restriction Point

The product (RB) of the retinoblastoma tumor suppressor gene (RB1) is expressed in all normal cells including quiescent and proliferating cells. RB functions in part to repress the E2F transcription factors. There are two classes of E2F genes that are responsive to RB. The activating E2Fs including E2F1, E2F2, and E2F3 promote expression of a large class of genes required for DNA synthesis. The repressor E2Fs include E2F4 and E2F5 and serve to repress E2F-dependent genes during quiescence. The activating and repressing E2Fs bind to the dimerization partner DP (TFDP1-3) to form sequence-specific DNA binding transcription factors. RB binding to the activating E2Fs serves to repress their transcriptional activity. RB can also bind to the repressor E2Fs. In addition to RB, p107 (RBL1) and p130 (RBL2) are two RB-like proteins that have strong preference for binding to the repressor E2F4 and E2F5. While bound to a repressor E2F, p130 and p107 also bind to a five-protein complex termed MuvB or LINC to form the DREAM (DP, RB-like, E2F and MuvB) complex (Sadasivam and DeCaprio, 2013). During quiescence, the DREAM complex functions to repress all E2F-dependent genes including genes induced by the activating E2Fs during the G1/S transition as well as genes expressed during the G2 and M phases of the cell cycle that are dependent on B-MYB (MYBL2) and FOXM1 (Figure 1(b)).

The repressor activity of the RB proteins is regulated by CDKs. During G1, cyclin D (CCND1, CCND2, and CCND3) heterodimerizes with CDK4 or CDK6 to form the active kinase. Cyclin D expression is dependent on RAS and MYC signaling (Yu *et al.*, 2005). As mentioned above, cyclin D levels increase during the progression phase of G1 (Jones and Kazlauskas, 2001). Later in G1, cyclin E (CCNE1) levels increase. Cyclin E binds specifically to CDK2 and also contributes to RB phosphorylation. Cyclin E-CDK2 phosphorylates RB on multiple CDK consensus sites resulting in release of hyper-phosphorylated RB from the activating E2Fs thereby enabling E2F-dependent gene expression. Once past this point, growth factors are no longer required for S phase entry. Therefore, expression and activation of cyclin E-CDK2 results in the hyper-phosphorylation of RB that is required to pass the restriction point (Figure 1(b)) (Planas-Silva and Weinberg, 1997).

Recently, it was reported that cyclin D-CDK4 could specifically phosphorylate RB on any one of 15 different serine or threonine residues that form a CDK consensus site (S/T)P. Strikingly, in the presence of active cyclin D-CDK4, a given molecule of RB is only phosphorylated on one of these 15 sites (Narasimha *et al.*, 2014). Apparently, mono-phosphorylation

of RB by cyclin D-CDK4 precludes additional phosphorylation by cyclin D-CDK4. In contrast, cyclin E-CDK2 can phosphorylate a single molecule of RB on many of these (S/T)P sites resulting in a hyper-phosphorylated RB (Figure 1(b)). Notably, mono-phosphorylated RB (cyclin D-CDK4 dependent) could bind to the activating E2Fs and repress their transcriptional activity while hyper-phosphorylated RB (cyclin E-CDK2 dependent) could not. Furthermore, it was demonstrated that mono-phosphorylated RB was specifically capable of repressing the activating E2Fs when cells had undergone DNA damage signaling. Although some of these models need to be further validated, the concept of singly phosphorylated RB, previously referred to as under- or hypo-phosphorylated RB, brings a new perspective to how RB responds to cyclin D-CDK4 during G1.

In any case, it is likely that un-phosphorylated RB as well as the DREAM complex is present in quiescent cells. However, once cells have been rendered competent for cell cycle entry, cyclin D-CDK4 activity promotes the mono-phosphorylation of RB during the progression phase. Later, cyclin E-CDK2 hyper-phosphorylates RB thereby releasing it from the activating E2Fs and enabling expression of genes required for DNA synthesis. Thus cyclin E activity directed toward RB enables a cell to pass the restriction point and become committed to cell cycle entry. This period of G1 when cells have committed to S phase entry after the restriction point, when RB is hyper-phosphorylated, but before DNA synthesis begins is referred to as the G1/S phase of the cell cycle (Figure 1(b)).

In addition to cyclins and CDKs, the CDK inhibitors play an important role in establishing and regulating the restriction point. There are two general classes of CDK inhibitors: the CDKN2 inhibitors including p16 INK4a (CDKN2A), CDKN2B, CDKN2C, and CDKN2D which inhibit CDK4/6 by preventing their binding to cyclin D, and the p21 (CDKN1A) class that includes p27 (CDKN1B) and p57 (CDKN1C) which bind to and inhibit kinase activity of the cyclin D-CDK4/6 and cyclin E-CDK2 complexes. During quiescence, p27 is highly expressed and binds to cyclin D-CDK4 to inhibit its kinase activity. p27 Levels decrease when cells are made competent for cell cycle progression through a pulse of PDGF (Agrawal *et al.*, 1996). As cyclin D levels increase during the progression phase they titrate the available p27, thereby enabling cyclin E-CDK2 to become active. Therefore, p27 plays a critical role in establishing quiescence and competence through its inhibition of cyclin D-CDK4/6 (Figure 1(b); Coats *et al.*, 1996). After cells progress past the restriction point, p27 becomes phosphorylated by cyclin E-CDK2 followed by ubiquitination by the SCF (SKP1, CUL1, F-Box)–SKP2 complex and subsequent proteasome mediated destruction during G1/S phase (Vlach *et al.*, 1997; Carrano *et al.*, 1999). In addition, p27 can become deactivated during the G1 progression phase when it is transported to the cytoplasm and undergoes ubiquitination by a distinct ubiquitin ligase (Kamura *et al.*, 2004).

The p21 CDK inhibitor also plays a critical role during the G1 phase of the cell cycle. Elevated p21 levels can bind to and inactivate cyclin E-CDK2 (Harper *et al.*, 1993). p21 Undergoes a significant increase in levels and fold change in response to p53 activation during cellular stress (Allen *et al.*, 2014). For example, shortened telomeres or double-stranded DNA breaks will activate ataxia telangiectasia mutated (ATM) to phosphorylate p53 which in turn decreases its affinity for the MDM2 ubiquitin ligase and

increases it to the co-activators p300 (EP300) and CBP (CREBBP). Increased p53 levels can be induced by shortened telomeres. Indeed, many studies of the restriction point used immortalized cells that presumably have increased telomerase activity or reduced p53 activity. Thus, elimination of the p53 and p21 restraining activity can overcome the need for the second pulse of growth factors (Zwang *et al.*, 2011).

The G1/S DNA damage checkpoint can be viewed as a point in the cell cycle when the cell has become fully committed to enter into S phase and past the restriction point, but is unable to enter S phase because cyclin E-CDK2 and cyclin D-CDK4 are inactivated by the p21 and p16, respectively and RB remains capable of binding to and repressing the activating E2Fs, thereby decreasing levels of factors required for DNA synthesis (Figure 1(b)). The DNA damage that induces p53 can be derived from a variety of sources. If the DNA damage or stress signals are repaired, cells can exit the G1/S checkpoint and reenter the cell cycle. If the damage is not repaired in a timely manner, cells will enter a senescent state where they remain viable but not capable of reentering the cell cycle. RB and p53 participate in establishing the senescent state. During senescence, cells have committed to proliferation and presumably have passed the restriction point with activation of the ERK signaling pathway but perhaps have not integrated PI3K signaling resulting in activation of p53 (Figure 1(b)).

In this discussion of the restriction point, emphasis was made on the events that occur in normal cells in response to growth factors. The timely and integrated coordination of signaling events is required for a normal cell to reenter the cell cycle from quiescence. The signaling pathways downstream of receptor tyrosine kinases, MAPK, PI3K, and CDKs combined with the restraining activities of RB and p53 must be highly regulated to enable cell cycle progression. These events are highly regulated in normal fibroblasts in culture but also in all of the many cell types present in tissues. Furthermore, components of these pathways are nearly always perturbed in cancer. Therefore, study of the events that contribute to establishment of the restriction point as well as what is required to enable cellular proliferation will continue to bring insights into normal development and disease processes.

Conclusions

1. The concept of the restriction point has evolved considerably since its initial description.
2. The restriction point occurs at a point in G1 when a normal cell no longer requires growth factors to enter S phase.
3. Cells can exit the cell cycle if cultured without growth factors during a brief period after mitosis.
4. Exit from the cell cycle can lead toward quiescence and terminal differentiation.
5. Growth factors at two steps are required to pass the restriction point.
6. The first step promotes RAS and MAP kinase signaling and leads to competence.
7. Competent cells are capable of slowly activating biosynthesis pathways.
8. The second step involves cyclin D, mono-phosphorylation of RB, and PI3K signaling.

9. Competence activates while progression deactivates p53 signaling.
10. Once cyclin E is activated and RB becomes hyper-phosphorylated, the cells have entered G1/S and made the commitment to DNA synthesis.

CDK Inhibitors in Normal and Malignant Cells

Cyclins, CDKs, and Cell Cycle Progression

The mammalian cell cycle is composed of four phases directed by the actions of Cyclin-cyclin-dependent kinase (CDK) complexes. The intensity of mitogenic or antimitogenic signals received by the cell directs a binary decision to proliferate or not. A checkpoint occurs at a restriction point late in the first growth phase (G1), and is largely governed by the gatekeeper protein Rb. Once this checkpoint is passed, normal cells irreversibly commit to replicate their DNA and will divide if replication is successful and die if it is not. The Cyclin-CDK holoenzyme complex comprises a regulatory Cyclin and a catalytic CDK that, once active will phosphorylate its protein substrates. There are four major mammalian Cyclins: Cyclin E, A, D, and B, each of which has more than one isoform and the CDK family contains 11 members. Sequential, tightly regulated increases in Cyclin gene expression and protein stability lead to successive peaks of Cyclin-CDK activity that direct cell cycle progression (see Figure 1). CDK protein and RNA levels remain largely constant across the cell cycle (Sherr and Roberts, 1999).

In response to mitogenic signals, such as epidermal growth factor receptor (EGFR) or Ras activation, genes encoding D-type Cyclins are induced, and Cyclin D-CDK4/6 complexes assemble in the cytoplasm (Sherr, 1993). D-type Cyclins act as growth factor sensors to direct the cell to exit quiescence and proliferate under favorable conditions. In quiescent cells, hypophosphorylated retinoblastoma protein (pRb) sequesters transcription factors E2F1-4 (Dyson, 1998) and inhibits induction of target genes required for DNA replication in S phase. Once Cyclin D-CDK4/6 complexes translocate to the nucleus, they initiate phosphorylation and inactivation of pRb. Later in G1, activated Cyclin E-CDK2 complexes further

phosphorylate pRb mediating release and activation of E2F to allow progression into S phase. During the second growth phase (G2), Cyclin A- and Cyclin B-CDK2 complexes maintain pRb in a hyperphosphorylated state until the cell exits mitosis (reviewed in Sherr and Roberts, 1999).

There are two CDK inhibitor protein families: the inhibitor of CDK4/6 (INK4) family, which includes homologous proteins p15^{INK4b} (Hannon and Beach, 1994), p16^{INK4a} (Serrano et al., 1993), p18^{INK4c} (Guan et al., 1994; Hirai et al., 1995), and p19^{INK4d} (Hirai et al., 1995; Chan et al., 1995) and kinase inhibitor proteins (KIP), comprising p21^{CIP1}, p27^{KIP1}, and p57^{KIP2}. In states of terminal cellular differentiation or unfavorable growth conditions, several inhibitors cooperate to halt cell cycle progression at various stages. INK4 family members act early in G1 to bind and inhibit Cyclin D-CDK4/6 complexes. Members of the CIP/KIP family of inhibitors have a broader target range and act largely to bind Cyclin E-CDK2 in G1 phase and Cyclin A-CDK2 in S phase, but may also inhibit Cyclin B/A-CDK2 in G2 phase under situations of cellular stress or DNA damage (reviewed in Sherr and Roberts, 1999; Sherr, 1993; Kim and Sharpless, 2006; Gil and Peters, 2006). The following will briefly review the function and regulation of the best understood CDK inhibitors, p15^{INK4b}, p16^{INK4a}, p21, and p27 in normal cells, their deregulation and potential prognostic significance in human cancers and their potential as markers/predictors of oncogenic pathway activation and responsiveness to targeted therapies.

The INK4 Family

Normal Function

p15^{INK4b} and p16^{INK4a} bind to CDK4 and CDK6 and allosterically inhibit the binding of Cyclin D, thus preventing activation of the complex. INK4 proteins interact with CDK4 and CDK6 through several ankyrin repeats which mediate protein-protein interaction. p15^{INK4b} and p16^{INK4a} are encoded at the *INK4a/ARF/INK4b* locus on chromosome 9p21, which is a common site of deletion or mutational inactivation in cancers (reviewed in Kim and Sharpless, 2006; Gil and Peters, 2006). Identification of the p16^{INK4a} tumor suppressor protein was prompted by genetic linkage studies showing that an inherited predisposition to melanoma could be traced back to a deletion at the *INK4a/ARF/INK4b* locus (Kamb et al., 1994; Nobori et al., 1994). p15^{INK4b} was discovered as a TGF- β induced mediator of cell cycle arrest (Hannon and Beach, 1994). Interestingly, the ARF, or alternate reading frame protein is also encoded at this locus, but translated in a different reading frame. ARF is also a cell cycle inhibitor, but largely controls p53 function in response to aberrant growth or oncogenic stress and does not function as a Cyclin-CDK inhibitor (reviewed in Kim and Sharpless, 2006; Gil and Peters, 2006).

Figure 1 Sequential upregulation of Cyclin CDKs governs progression through the cell cycle. CDKs of the INK4 and CIP/KIP family critically regulate cell cycle transitions.

Regulation of p15^{INK4b} and p16^{INK4a} Levels

p15^{INK4b} and p16^{INK4a} are encoded by the *CDKN2B* and *CDKN2A* genes on the *INK4a/ARF/INK4b* locus, and both are tightly regulated by transcriptional mechanisms. The genes encoding p15^{INK4b} and p16^{INK4a} are induced in response to oncogenic Ras signaling, and bring about p16^{INK4a}-mediated senescence as a means of protecting cellular integrity. Ras activation leads to subsequent MEK/ERK activation, and ERK-mediated induction of Ets1/2 may mediate in part the induction and increase in p16 expression following Ras activation (Ohtani *et al.*, 2001). In response to TGF- β signaling, SMADs 2 and 4 induce *CDKN2B* to mediate growth arrest in TGF- β -responsive cells (Hannon and Beach, 1994). These genes are also subject to epigenetic regulation: to prevent premature senescence, the genes encoding p16^{INK4a}, p15^{INK4b}, and ARF are repressed by T-box proteins and by the polycomb group genes (PcG) BMI1, Cbx7, and Me18, which epigenetically silence genes by remodeling chromatin. Loss of BMI1 has been associated with reduced stem cell populations due to increased expression of p16^{INK4a} (reviewed in Kim and Sharpless, 2006; Gil and Peters, 2006). Methylation of the gene encoding p16^{INK4a} is significantly correlated with blastic bone marrow involvement, and sequential analyses have shown that *CDKN2B* gene methylation increases with myelodysplastic disease evolution toward AML. These data suggest that *CDKN2B* methylation may allow leukemic cells to escape inhibitory signals from the bone marrow environment (Quesnel *et al.*, 1998).

In normal hematopoietic cells, TGF- β signaling inhibits proliferation. Compared to solid malignancies, leukemic malignancies show more frequent *CDKN2B* gene methylation and inactivation compared to *CDKN2A*. Leukemic cells that lose sensitivity to TGF- β signaling generally have *CDKN2B* gene methylation, and this suggests that p15^{INK4b} inactivation is important for marrow blast proliferation in myeloid malignancies (reviewed in Quesnel and Fenaux, 1999).

Functions Independent of CDK Inhibition

Senescence/stem cell self-renewal

Several groups have shown that p16^{INK4a} levels increase markedly in aging tissues, providing evidence that pre-programmed senescence and aging are intimately linked to the cell machinery (Kim and Sharpless, 2006). p16^{INK4a} mediates G1 arrest during normal prostate epithelial cell senescence (Sandhu *et al.*, 2000). Aging is characterized by a reduced ability of stem cells to regenerate lost or damaged cells, and it has been suggested that an increase in p16^{INK4a} leads to the decline of replicative potential of stem cells (reviewed in Kim and Sharpless, 2006; Sherr and Roberts 1999; Warfel and El-Deiry 2013). Hemopoietic stem cells (HSCs) from *CDN2A* $-/-$ *ARF* $-/-$ mice have an increased ability to serially transplant and repopulate irradiated recipient mice (Stepanova and Sorrentino, 2005). *CDKN2A* knockout causes loss of the age-induced decline in proliferation in HSCs, neural stem cells, and pancreatic islets (reviewed in Kim and Sharpless, 2006).

Mouse models have provided powerful tools to elucidate CDK inhibitor function in development and tumorigenesis. *CDKN2A* $-/-$ animals develop normally, but form spontaneous tumors at an early age (Serrano *et al.*, 1996), while

p15^{INK4b} $-/-$ animals also develop normally, but do not display a predisposition to tumor formation (Roussel, 1999). Notably, mutations or selective deletions of the *CDKN2B* gene have not been frequently identified in solid human tumors. Thus, it appears that p15^{INK4b} may not be a tumor suppressor, but serves a redundant function to inhibit cell cycle.

The CIP/KIP Family

Normal Function

p21^{CIP1}, encoded by *CDKN1A*, and p27^{KIP1} encoded by *CDKN1B* (hereafter p21 and p27), are highly homologous proteins that regulate the cell cycle by binding directly to both their Cyclin partners, largely E and A-type Cyclins, and to the catalytic cleft of their target CDKs, acting as competitive inhibitors for CDK substrates. Both CDK and Cyclin binding motifs are located in the N-terminal regions of p21 and p27 and are highly conserved (reviewed in Sherr and Roberts, 1999). Efficient CIP/KIP-mediated complex inhibition requires inhibitor binding to both its target Cyclin and CDK simultaneously (Vlach *et al.*, 1997; Chu *et al.*, 2007). p21 and p27 both bear a conserved C-terminal nuclear localization sequence, ensuring that the newly translated protein is directed to CDK targets in the nucleus (Zeng *et al.*, 2000; Rodriguez-Vilarrupla *et al.*, 2002). p21 was discovered as a growth inhibitor in senescent cells (Noda *et al.*, 1994), in cells arrested by p53 in response to DNA damage (Dulic *et al.*, 1994; El-Deiry *et al.*, 1993), and through a yeast two-hybrid screen for inhibitors of CDK2 (Harper *et al.*, 1993). p21 is abundantly expressed in proliferating cells, and is usually reduced or absent in quiescent cells (see Sherr and Roberts, 1999 for review). p21 is a transcriptional target of p53 and is called into action to halt cell cycle progression in response to DNA damage. While p27 appears to govern cell cycle progression in all cells, p21 appears to play a CDK inhibitor role largely as a stress reader, and it is induced by DNA damage, hypoxia, and redox stressors (Sherr and Roberts, 1999). Interestingly, p21 null mice develop normally, although p21 null embryonic fibroblasts display a reduced ability to promote G1 arrest following DNA damage. This is consistent with a role for p21 primarily in checkpoint control, rather than as regulator of progenitor commitment.

p27 was first identified as a CDK2-inhibitor in TGF- β -treated cells and is regulated by growth inhibitory cytokines and by contact-inhibition (Koff *et al.*, 1993; Polyak *et al.*, 1994a,b; Slingerland *et al.*, 1994; Hengst *et al.*, 1994). Both p21 and p27 appear to play critical roles to govern tissue proliferation during development and are upregulated to mediate cell cycle arrest. Unlike p21, p27 is strongly expressed in nonproliferating cells and critically regulates both quiescence and G1 progression. Mice lacking p27 display multi-organ hyperplasia and increased body size, and haploinsufficient animals are susceptible to carcinogen-induced tumors. Thus, p27 acts to control both cell proliferation and tissue expansion (reviewed in Vidal and Koff, 2000). Knock-in mice expressing a Cyclin-CDK-binding defective mutant p27 (p27^{CK-}) show increases in progenitor cell self-renewal in multiple tissues including pituitary, intestine, and bronchial

epithelium. p27^{CK-}-knock-in animals have increased bronchoalveolar stem cells and develop spontaneous lung tumors (Besson *et al.*, 2007).

p21/p27 double null mice display higher levels of spontaneous pituitary adenomas, pheochromocytomas, and thyroid adenomas, and have delayed incidence of radiation-induced thymic lymphoma (Garcia-Fernandez *et al.*, 2011). p15/p21 null mice display higher fibrosarcomas and rhabdomyosarcomas (Martin-Caballero *et al.*, 2004). p16/p19/p27 null mice show a significant increase in mortality due to accelerated development and metastasis of T-cell lymphoma (Martin-Caballero *et al.*, 2004). In contrast, p16/p19/p21 null mice do not have increased mortality but do develop fibrosarcomas (Martin-Caballero *et al.*, 2004). These phenotypes demonstrate the oncogenic cooperation between defects in INK4 and CIP/KIP family members.

Regulation

For both p21 and p27, key phosphorylation events have been identified that regulate their levels, activities, and intracellular localization. Both p21 and p27 act in the nucleus to inhibit CDKs (Connor *et al.*, 2003; Cmielova and Rezacova, 2011). During G1 progression, different phosphorylation events regulate degradation of these CIP/KIPs. Extracellular regulated MAP kinase (ERK) phosphorylates p21 at threonine 57 (T57) and serine 130 (S130) to regulate p21 degradation (Hwang *et al.*, 2009). p21 stability is increased by phosphorylations at T145 and S146 by AKT, and by p38 or JNK (Jun N-terminal kinase) at S130 (Hwang *et al.*, 2009). There are at least two major pathways governing p27 proteolysis. In early G1, mitogens promote S10 phosphorylation of p27 (Boehm *et al.*, 2002; Deng *et al.*, 2004), which facilitates CRM1-mediated p27 nuclear export (Connor *et al.*, 2003; Ishida *et al.*, 2000, 2002; Rodier *et al.*, 2001) and subsequent degradation. The best characterized proteolytic mechanism governing p27 is mediated by SCF^{Skp2} (S-phase kinase associated protein 1 (SKP1)/Cullin/F-Box protein: S-phase kinase associated protein 2 (Skp2)) complex, whose binding to p27 is stimulated in late G1 by p27 phosphorylation by Cyclin E or A-Cdk2 at threonine 187 (T187) (Nakayama and Nakayama, 2006). While free, active Cyclin E or A-CDK2 can phosphorylate CDK-bound p27 at T187 efficiently *in vitro*, p27-bound CDK2 is catalytically inactive (Larrea *et al.*, 2008). p27 contains three tyrosines at residues 74, 88, and 89 within its Cdk-inhibitory domain. Y88 is part of a 310-helix in p27 that inserts into the CDK2 catalytic cleft and displaces ATP (Russo *et al.*, 1996). p27 phosphorylation by Src (Chu *et al.*, 2007) and Abl (Grimmler *et al.*, 2007) at tyrosine 74 (Y74), Y88, and Y89 causes its ejection from the catalytic cleft of Cdk2 (Chu *et al.*, 2007). Thus, p27^{Y88}-bound Cyclin E-Cdk2 is no longer inhibited and can phosphorylate p27 at T187 to activate SCF^{Skp2}-mediated p27 proteolysis in late G1/S (Chu *et al.*, 2007; Grimmler *et al.*, 2007). While Y88 is highly conserved among all CIP/KIP family CDK inhibitors, including human p21 and p57 proteins, it is not clear whether Src family kinase-mediated phosphorylation governs p21 and p57 stability in an analogous manner.

C-terminal phosphorylations also critically regulate levels and localization of both p21 and p27. p27 can be phosphorylated by PI3K-effector kinases, AKT, SGK, and RSK at

threonine residues T157 and T198 (Wander *et al.*, 2011). T157 of p27 is located within its nuclear localization sequence and phosphorylation at this site delays its nuclear import into the nucleus, shifting the pool of p27 toward cytoplasmic localization (Wander *et al.*, 2011). Phosphorylation at T198 stabilizes p27 in the cytoplasm (reviewed in Larrea *et al.*, 2009). Similarly, p21 can be phosphorylated by AKT at T145 (the site homologous to T157 in p27), leading to accumulation in the cytoplasm and loss of its CDK-inhibitory action in the nucleus (reviewed in Warfel and El-Deiry, 2013; Weiss, 2003). Growing evidence suggests that the cytoplasmic mislocalization of both of these proteins leads to pro-oncogenic gain of function (Wander *et al.*, 2011; Besson *et al.*, 2004, 2008) and these are reviewed below.

Although p27 mRNA levels are constant throughout G1-S phase, its translation decreases dramatically upon G0 exit (reviewed in Chu *et al.*, 2008); p21 mRNA levels, however, are tightly controlled by transcriptional regulators, most of which induce p21 transcription through Sp1-3 sites in the p21 promoter. These include p53, TGF- β , NGF (nerve growth factor), and BCRA1. c-Myc, however, inhibits p21 transcription to blunt p53-dependent induction of p21 in response to DNA damage. Under conditions of cellular stress, p21 mRNA can be stabilized to prevent inappropriate cell cycle entrance through binding of the transcription factor ZONAB to its 3' UTR. Following translation, the p21 protein is stabilized by HSP90, preventing its immediate degradation if otherwise left unbound (reviewed in Warfel and El-Deiry, 2013).

Functions Independent of CDK Inhibition

D-type Cyclin/CDK4/6 assembly and nuclear import

Paradoxically, p21 and p27 both act to enhance Cyclin-CDK complex formation and thereby promote proliferation. Cytoplasmic p21 and p27 both increase assembly of Cyclin D-CDK4/6 and stabilize these complexes (LaBaer *et al.*, 1997). Since neither CDKs4/6, nor D-type Cyclins bear a nuclear localization sequence (NLS), the associated KIP is required for nuclear import (reviewed in Warfel and El-Deiry, 2013; Weiss, 2003). Cyclin D-bound and Cyclin E-bound p27 have different phospho-isoform patterns (Ciarallo *et al.*, 2002) and p27 phosphorylation by AKT at T157 and T198 facilitates p27 assembly of Cyclin D-CDK4/6 (Larrea *et al.*, 2008; James *et al.*, 2007). While high p21 levels are required to inhibit G1-S Cyclin-CDKs, low p21 levels are sufficient to promote Cyclin D-CDK4 complex formation following mitogenic stimulation (Warfel and El-Deiry 2013; LaBaer *et al.*, 1997).

p21 enhances proliferation as a target of PI3K and was shown to mediate the pro-proliferative effects of IGF-1 (Dupont *et al.*, 2003). In addition, cytosolic, AKT-phosphorylated p21 increases proliferation in Her2/neu over-expressing cells (reviewed in Weiss, 2003). Introduction of an NLS-deficient p21 localized primarily to the cytoplasm, increased cell cycle progression in vascular smooth muscle cells and caused protection from apoptosis in monocytes. Furthermore, Paclitaxel treatment can increase cytosolic p21 levels in squamous carcinoma cells, thus resulting in increased proliferation (reviewed in Weiss, 2003). p27 also appears to promote tumor progression in PI3K activated cancers.

Pro-oncogenic actions of p27^{pT157pT198} in cancers are reviewed below.

Apoptosis

Following DNA damage, p53 is upregulated and directs either a cytostatic response, inducing p21 to halt proliferation, or a response leading to programmed cell death. Factors mediating this decision by p53 are not completely understood, however, Myc and its corepressor Miz-1 can be recruited to the p21 promoter to repress its transcription and switch the p53 response from cytostatic to apoptotic in response to DNA damage (Seoane *et al.*, 2002). p21 may also coordinate cell cycle arrest permitting time for DNA repair, by inhibiting the activation of pro-apoptotic factors p38, JNK, ASK1, and SAP (reviewed in Weiss, 2003). ETS-1 cooperates with p300 to activate p21 transcription and protect vascular smooth muscle cells from undergoing apoptosis (Zhang *et al.*, 2003). p21 itself is targeted during apoptosis, where caspase 3 cleaves off its NLS and relocates p21 to the cytoplasm to drive growth-arrested cells into apoptosis (Jin *et al.*, 2000).

Differentiation/senescence

Differentiation and senescence are both characterized by a stable exit from the cell cycle. While p27 activates differentiation pathways and p16^{INK4a} activates senescence pathways, p21 appears to play a role in both. The differentiation hormone vitamin D3, via its receptor, induces p21 transcription, and overexpression of both p21 and p27 can lead to terminal differentiation in monocytes/macrophages (Liu *et al.*, 1996). Cytoplasmic localization of p21 appears to drive differentiation in monocytes and neurites through poorly defined mechanisms (Tanaka *et al.*, 2002; Asada *et al.*, 1999). p21 can act as an initial, temporary mediator of senescence-like arrest in response to cellular stress or DNA damage, followed by a more permanent upregulation of p16^{INK4a} if the cell does not reenter cell cycle (Roninson, 2002; Muthna *et al.*, 2010). p21 is a key mediator of G1 arrest during the proliferative senescence of normal human mammary epithelial cells accompanying telomere shortening (Sandhu *et al.*, 2000; Noda *et al.*, 1994). p21 overexpression induces a senescence-like state in HeLa cells, and its attenuation inhibits senescence (reviewed in Weiss, 2003).

p27 appears to regulate progenitor expansion and differentiation in various normal tissue types. It is shown to be critical for xenopus neuronal differentiation (Vernon *et al.*, 2003, 2006; Nguyen *et al.*, 2006, 2007), and knockdown of Xic1, the p27 homolog in *Xenopus*, causes loss of muscle differentiation. Xic1 is required at a point prior to terminal muscle differentiation and cell cycle arrest, and may act through modulation of transcription. Xic1 increases the activity of myogenic transcription factor, MyoD (Vernon and Philpott, 2003), to drive myogenic commitment through cell cycle-independent actions (Vernon and Philpott, 2003; Messina *et al.*, 2005). Xic1 also plays a Cyclin-CDK-independent role to drive cardiac myotome differentiation (Movassagh and Philpott, 2008). During bone differentiation, p27 cooperates with p130 to promote endochondral ossification (Yeh *et al.*, 2007).

Transcriptional regulation

There is increasing data to suggest that both p21 and p27 may modulate gene expression by binding a number of transcription factors. Transfection of a Cyclin-CDK-binding defective p21 led to p21 binding to and inhibiting E2F1 activity, suggesting that p21 may function to modulate this important transcription factor. Following stimulation with leukemia inhibitor factor (LIF), p21 can bind and inhibit STAT3/CBP (CREB binding protein) transcriptional activity (reviewed in Warfel and El-Deiry, 2013).

p27 was recently shown to act as a transcriptional corepressor in a complex with other transcriptional repressors p130, E2F4, HDAC1, and SIN3A (Pippa *et al.*, 2012). Putative p27-repressed target genes identified by ChIP/CHIP assays included targets that govern cell proliferation and tissue expansion (Pippa *et al.*, 2012). Sox2 is a critical embryonic stem cell (ES) transcription factor that maintains ES self-renewal (Marson *et al.*, 2008) and may also drive cancer stem cell expansion (Bass *et al.*, 2009; Leis *et al.*, 2011). SOX2 is corepressed by p27 in that p27 binds the main SOX2 regulator site, SOX2-SRR2, located 4KB downstream of the coding exon to corepress SOX2 together with p130, E2F4, and SIN3A (Li *et al.*, 2012). Thus, p27 may carry out a spectrum of developmental roles via transcriptional actions. The gene targets of p27 that govern differentiation and how they may be disrupted in cancer remain to be elucidated.

Stem cell self-renewal

p21 and p27 may contribute to regulation of stem cell populations. p21 plays a role in maintaining a quiescent stem cell population and preventing epithelial-mesenchymal transition (EMT) and cancer stem cells (CSC) expansion *in vivo* in Ras- or c-Myc-driven tumorigenesis (reviewed in Warfel and El-Deiry, 2013). p21 knockout mice had increased hematopoietic stem cell proliferation, indicating that p21 may restrain HSC self-renewal. It is noteworthy that p27 null animals exhibit multi-organ hyperplasia and hypertrophy and spontaneous neoplasia (reviewed in Chu *et al.*, 2008), suggesting p27 normally acts to limit organ size in embryogenesis. Notably, this phenotype is phenocopied in p27^{CK-} knock-in, reflecting the loss of CDK-inhibitory action. In addition, in p27CK-knock-in animals, loss of CDK inhibition and a CDK-independent gain of p27 function appear to perturb normal stem cell homeostasis and cause expansion of progenitor/stem cells in several tissues, increased bronchoalveolar stem cells and spontaneous lung tumor formation (Besson *et al.*, 2007). These intriguing findings suggesting that p27 may have cell cycle-independent roles to regulate stem expansion in many tissues (Besson *et al.*, 2007).

Prognostic Significance of CDK Inhibitor Deregulation in Human Cancers

Deregulation of the CDK inhibitors is one of the hallmarks of cancer. While mutations/deletions of genes encoding p15^{INK4b}/p16^{INK4a} are frequent in hemopoietic leukemia, loss of p16^{INK4a} in solid tumors is also reported. Malignancies of many tissues exhibit loss of CIP/KIP proteins and genetic

Figure 2 Schematic showing different human malignancies affected by changes in CDK inhibitors. The *INK4a* and *INK4b* alterations occur mostly at the genetic level (deletions/mutations), while changes in KIP/CIP levels and localization have potential for prognostic impact in cancers arising from the tissue sites shown.

changes leading to loss of $p15^{INK4b}/p16^{INK4a}$, and these are reviewed below (Figure 2).

INK4 Family

$p16^{INK4a}$ plays a role as a classic tumor suppressor, and homozygous deletion of chromosome 9p21, encoding the *INK4a/ARF/INK4b* locus, is one of the most frequent cytogenetic events in a wide variety of human malignancies (Kim and Sharpless, 2006; Beroukhi et al., 2010; Bignell et al., 2010). *INK4a/ARF/INK4b* locus deletion has been observed in melanoma (Kamb et al., 1994), pancreatic adenocarcinoma (Caldas et al., 1994; Wilentz et al., 1998; Rozenblum et al., 1997), glioblastoma (Moulton et al., 1995), acute lymphoblastic leukemia (Okuda et al., 1995), non-small cell lung cancer (Belinsky et al., 1998), and bladder carcinoma (Williamson et al., 1995). Its deletion or mutation leads to cellular immortalization (Hara et al., 1996; Alcorta et al., 1996), and can predispose to melanoma. In melanomas, the mutant form of B-Raf strongly induces expression of *CDKN2A*, and as a result, melanomas with increased B-Raf mutation usually have deletions at the *INK4A* locus (Pollock et al., 2003). In human cancers, deletions leading to $p16^{INK4a}$ loss most always cause loss of $p15^{INK4b}$ also and to date it is not clear how each may contribute independently to tumor formation or progression.

Since genetic loss of $p16^{INK4a}$ is tumorigenic in mice, and mutation or deletion of $p15^{INK4b}$ and $p16^{INK4a}$ occurs frequently in human cancers, several studies have investigated if loss of $p15^{INK4b}/p16^{INK4a}$, either genetically or at the protein level, is a prognostic indicator of poor overall survival or shortened disease-free survival. In acute lymphoblastic leukemia, homozygous deletions in either $p15^{INK4b}/p16^{INK4a}$, or $p16^{INK4a}$ alone, were identified as an independent predictor of relapse and death, but a second study failed to confirm this

finding (Tsihlias et al., 1999). In non-Hodgkin's lymphoma, NSCLC, and melanoma, loss of either the $p16^{INK4a}$ gene or protein has an independent prognostic significance for poor overall survival and disease-free survival (reviewed in Tsihlias et al., 1999).

CIP/KIP Family

Loss of p21, and particularly p27, have been frequently reported to be of prognostic importance in many human cancers. The genes encoding these CDK inhibitors are rarely deleted or mutated in cancer (reviewed in Chu et al., 2008; Vidal and Koff, 2000). Notably, novel mutations in *CDKN1B* have been recently brought to light in whole genome sequencing of breast cancers, but their functional significance remains to be characterized (Stephens et al., 2012). While loss of these CDK inhibitors through deregulated proteolysis or translational inhibition (Chu et al., 2008) would promote tumor cell growth, both p21 and p27 appear to acquire pro-oncogenic roles when misregulated in cancers (Warfel and El-Deiry, 2013; Chu et al., 2008; Abbas and Dutta, 2009). The mislocalization of p27 to the cytoplasm, seen in up to 60% of cancers, leads to a gain of function in which cells acquire increased motility, invasion, and metastasis capability (Larrea et al., 2008; Besson et al., 2004; Wander et al., 2013). Mislocalization of p21 to the cytoplasm has been reported in several tumor types, including breast (Xia et al., 2004; Winters et al., 2003; reviewed in Abbas and Dutta, 2009), hepatocellular carcinoma (reviewed in Abbas and Dutta, 2009), testicular cancer (Koster et al., 2010), and acute leukemia (Schepers et al., 2003). Both p21 and p27 can bind to and inhibit RhoA activity in the cytoplasm. The same phosphorylation events that promote mislocalization of p21 and p27 enhance their binding to RhoA, which impairs RhoA-ROCK activity leading

to loss of acto-myosin stability and increased cell motility (Besson *et al.*, 2004; Lee and Helfman, 2004; Larrea *et al.*, 2009; see Figure 3).

The RhoA binding effect of cytoplasmic p27 is not the only mechanism whereby p27 drives cell invasiveness. AKT is a downstream effector of PI3K, which is commonly activated in many cancers (Wander *et al.*, 2011). Not only does oncogenic PI3K/mTOR activation drive p27 phosphorylation at T157 and T198 to increase cell motility (Larrea *et al.*, 2009), cytoplasmic p27 is a major mediator of metastasis downstream of PI3K/mTOR signaling. p27 knockdown had the same effect as PI3K/mTOR inhibition to dramatically reduce bone metastasis (Wander *et al.*, 2013). We recently reported a novel mechanism whereby C-terminally phosphorylated p27 contributes to cancer progression, linking PI3K activation to STAT3 activation, EMT and cancer metastasis. We describe an oncogenic feed-forward loop in which p27^{T157}p27^{T198} binds JAK2 promoting STAT3 recruitment and activation. STAT3-mediated *TWIST1* induction drives a p27 dependent EMT and feeds forward to further activate AKT contributing thereby to acquisition and maintenance of metastatic potential (Zhao *et al.*, 2015; see Figure 3).

The loss of nuclear p27 protein predicts poor prognosis in many cancers (Chu *et al.*, 2008). Indeed, virtually all human cancers show either a reduced nuclear p27 level or mislocalization of p27 to the cytoplasm (reviewed in Larrea *et al.*, 2009). p27 immunohistochemical staining showed low nuclear p27 staining is prognostic of poor overall survival or reduced disease-free survival in breast, prostate, colon, gastric, non-small cell lung cancer, esophageal cancer, glioma, sarcoma, and hematopoietic malignancies. Further work has shown that cytoplasmic p27 mislocalization may also have prognostic importance (Wander *et al.*, 2011). A recent analysis of p27 in node positive breast cancers showed increased cytoplasmic p27 correlated with increased node positivity and decreased survival (Wander *et al.*, 2013).

Although p21 loss has been reported to enhance metastatic spread (Warfel and El-Deiry, 2013), the role of p21 as a prognostic marker for disease progression is unclear. Several studies in breast cancer, melanoma, gastric cancer, endometrial cancer, and head and neck cancer have reported conflicting outcomes based on p21 staining (reviewed in Tsihlias *et al.*, 1999). However, cytosolic p21 staining was recently correlated with both increased Her2 (c-erb2/neu) expression and poor patient outcome (Winters *et al.*, 2003). Since the prognostic value of p21 expression in cancer may be tumor type specific, further evaluation is needed before it can be applied in the clinic.

CDK Inhibitors as Predictors of Drug Response

Since p21 and p27 restrain the cell cycle in normal cells, one would not want to target their normal function therapeutically for cancer. However, there may be circumstances, particularly where these CDK inhibitors gain oncogenic function through aberrant C-terminal phosphorylations, in which targeting these proteins or their upstream activators might be therapeutically useful. Since expression of p21 delays or prevents apoptosis, targeting p21 in DNA-damaged cells may prove

synthetically lethal with chemotherapeutic agents in cancer cells with deregulated p53 or activated anti-apoptotic mechanisms. Antisense oligodeoxynucleotide (ODN)-mediated p21 knockdown has been tested *in vitro* and subcutaneous injection of p21 ODN caused attenuation of Met-1 breast cancer growth *in vivo* (Fan *et al.*, 2003). Further work is required to permit therapeutic application of p21 knockdown by ODN or gene therapy in the clinic. p21 expression levels and localization may also help to determine which drugs to give for individual tumor types. Antisense p21 ODN or gene therapy may prove beneficial, particularly in combination with AKT inhibition in tumors with cytoplasmic p21 on immunohistochemical (IHC) staining. Cancers with disrupted p21 were found to be more sensitive to chemotherapeutic agents or DNA-damaging stimuli (Alpan and Pardee, 1996).

Predictive factors for response to specific therapies are arguably more important than prognostic factors since they influence treatment decisions. Although there is abundant evidence that p27 loss or cytoplasmic mislocalization are of poor prognostic importance, p27 staining may have its greatest utility in directing the choice of targeted therapy for human malignancies (Martin-Caballero *et al.*, 2004). Several molecular targeting drugs impact p27 by inhibiting upstream signaling. The BCR-ABL kinase, commonly expressed in chronic myelogenous leukemia, reduces p27 levels through constitutive tyrosine phosphorylation and subsequent accelerated proteolysis. Treatment of chronic myeloid leukemia (CML) cells with imatinib restores p27 levels and inhibits proliferation. Furthermore, p27 levels are stabilized in Her2-overexpressing breast cancers and EGFR-overexpressing lung cancers following treatment with trastuzumab and gefitinib, respectively. In a recent study, treatment of breast cancer cells with the EGFR/ErbB-2 inhibitor lapatinib increased p27 and reduced tumor proliferation (D'Alessio *et al.*, 2010). MEK inhibition increased p27 to induce growth arrest in melanoma models, as well as human pancreatic cancer lines driven by activated Ras. Taken together, these findings suggest that effective drug-mediated interdiction of pathways driving Src activation and p27 proteolysis may be effectively monitored by testing for posttreatment upregulation of nuclear p27.

In hormone-sensitive tumors, drug resistance is usually an inevitable outcome, and p27 may be involved in mediating resistance to antiestrogen therapies. Both preclinical studies and analysis of p27 in breast cancers of patients in clinical trials suggest that high nuclear p27 may predict responsiveness to hormonal therapy (Porter *et al.*, 2006; Pohl *et al.*, 2003). In estrogen-responsive tumors, estrogen binding to the ER promotes p27 proteolysis and Cyclin E-CDK2 activation, driving cell cycle progression. In sensitive ER-positive breast cancers, ER-blocking drugs (tamoxifen and fulvestrant) and aromatase inhibitors oppose estrogen signaling and stabilize p27 to inhibit proliferation and growth. Interestingly, high Src activation correlates with reduced p27 in human breast cancers, and Src inhibition increased p27 and restored tamoxifen sensitivity in resistant breast cancer lines. Dual targeting of estrogen receptor, with antiestrogens, and oncogenic Src signaling increases p27 levels and caused greater G1 arrest and xenograft tumor growth inhibition *in vivo*, and delayed emergence of drug resistance compared with that observed with either drug alone in both breast (Chen *et al.*, 2009) and ovarian cancer models (Simpkins

Figure 3 Both p21 and p27 are phosphorylated by oncogenic PI3K pathway effector kinases. These phosphorylations lead to cytoplasmic mislocalization (p27pT157, p27pT198, and p21pT145), protein stabilization (p27pT198 and p21pS146), and to acquisition of oncogenic properties including RhoA-ROCK1 inactivation and increased cell motility (both p21 and p27). Cyclin D-CDK activation and cell cycle progression and, in the case of p27, induction of an EMT phenotype to promote tumor metastasis.

et al., 2012). These data provided a novel rationale for the use of Src inhibitors together with antiestrogens for ER+ breast and ovarian cancers. Currently, clinical trials are underway to test the potential efficacy of combined Src and aromatase inhibition in postmenopausal ER+ breast cancer (Pegram and Slingerland, unpublished data).

In up to 60% of human breast cancers, hyperactivation of PI3K/mTOR signaling drives C-terminal phosphorylation of p27 at T157 and T198, which promotes cytoplasmic p27 mislocalization, increased invasiveness, EMT activation, and greater metastatic potential in a variety of cancers (Larrea *et al.*, 2008; Wander *et al.*, 2013). While early clinical trials with rapamycin and its analogs were met with limited success, due to incomplete inhibition of mTORC1 signaling, pure mTOR catalytic site inhibitors or dual PI3K/mTOR kinase inhibitors have shown great potential in preclinical models and early clinical trials (reviewed in Martin-Caballero *et al.*, 2004). The presence of cytoplasmic p27 in human cancer tissue may herald PI3K pathway activation and potential for PI3K/mTOR inhibitors to restore normal p27 function.

Concluding Remarks

Mammalian CDK inhibitors were first described a little over two decades ago and have illuminated fundamentals of cell cycle regulation and their study has yielded critical insights into mechanisms leading to malignant cell growth. Both INK4 family members and CIP/KIP family members are frequently functionally misregulated in human cancers, either through genetic changes (*CDKN2A* and *CDKN2B*) or through changes in phosphorylation, stability, localization, and function in the case of p21 and p27. While many studies have investigated the potential prognostic value of these alterations in various human malignancies, changes in CDK inhibitors may prove to be useful predictors of oncogenic pathway activation and potential for targeted therapy responses.

Introduction

The cell cycle is a series of ordered biochemical events resulting in division of a mother cell into two identical daughter cells. This process requires the accurate duplication of DNA and equal segregation of chromosomes into each daughter cell, and it must be tightly regulated throughout the life span of complex organisms in order to prevent the unrestrained proliferation of damaged cells (i.e., cancer). Proper cell cycle progression is monitored by checkpoints, surveillance mechanisms that ensure the completion of each cell cycle phase and maintenance of genome integrity (Malumbres and Barbacid, 2009; Sherr, 2004). They are enforced by tumor suppressor proteins that arrest the cell cycle, enabling time for the cell to repair mistakes before reentering the cycle, or eliminate cells (e.g., by programmed cell death (apoptosis)) if the damage is intolerable. Two of the most important tumor suppressors are the retinoblastoma (RB1) and p53 proteins, which are activated by the products of the *INK4a/ARF* locus, p16INK4a and the alternative reading frame protein (ARF), respectively (Levine and Oren, 2009; Sherr, 2001). This review takes a historical look at the discovery and study of *INK4a/ARF*. It begins with a consideration of fundamental mechanisms controlling the cell cycle, highlighting where and how p16INK4a and ARF exert their anti-proliferative effects, followed by an analysis of their individual and interconnected roles in cancer. Growing evidence that the *INK4a/ARF* locus plays a pivotal role in other important aspects of normal biology will also be discussed.

Control and Significance of G1–S Phase Progression in Mammals

The 1990s was a time of rapid advancement in our understanding of the mammalian cell cycle, particularly the events controlling the first Gap period (G1 phase) and mechanisms by which cells begin DNA synthesis (S phase). Building of earlier studies of cyclins and cyclin-dependent kinases (Cdks) in yeast and *Xenopus*, we learned that the mammalian D-type cyclins (D1, D2, and D3) are regulatory subunits whose expression is maximally induced by mitogens in mid-G1 phase, at which time they form active serine/threonine kinases with their catalytic partners, Cdk4 or Cdk6 (Hunter and Pines, 1994; Malumbres and Barbacid, 2009; Sherr and Roberts, 2004). Those holoenzymes promote G1 to S phase progression by phosphorylating and inactivating the RB1 tumor suppressor protein (Figure 1(a)). RB1 phosphorylation, first by cyclin D-Cdk4/6 followed by cyclin E-Cdk2 and cyclin A-Cdk2 kinases, results in the release of E2F transcription factors from inhibitory RB1 complexes (Harbour and Dean, 2000). Once free, activated E2F proteins stimulate the expression of

numerous genes required for DNA replication, permitting cells to enter and progress through S phase. Interestingly, RB1 has two relatives, p107 and p130, that act similarly although their tissue distribution varies and only RB1 is commonly mutated in human cancers (Burkhardt and Sage, 2008).

G1 phase cyclins (principally D and E) and their partners (Cdks 2, 4, and 6) are rate-limiting in promoting cell cycle progression. Their overexpression in cultured cells shortens G1 phase and accelerates S phase entry, whereas their loss, depending on the cell type, prevents cell cycle progression (Sherr and Roberts, 2004). Moreover, many human cancers have gene amplifications, mutations, or translocations that elevate the expression and activity of these cyclins and Cdks (Malumbres and Barbacid, 2009). Mimicking those effects in mice causes tumor development *in vivo*. For example, artificial overexpression of cyclin D1 in mammary epithelial cells using the mouse mammary tumor virus promoter (MMTV) causes breast cancer in MMTV-D1 transgenic mice (Wang *et al.*, 1994). Conversely, mice lacking cyclin D1 are protected from breast cancer in animals with activated *Ras* or *Her2/neu/ErbB2* oncogenes (Lee and Sicinski, 2006). Such studies have established that elevated cyclin D-Cdk4/6 and E-Cdk2 activities are key drivers of tumorigenesis.

As a result, investigators have sought to understand the mechanisms that normally restrict cyclin D-Cdk4/6 and E-Cdk2 kinase activities in non-transformed cells and define how

Figure 1 The *INK4a*–RB1 anti-proliferative pathway. (a) The upregulation of cyclin D1 by mitogens promotes formation of D1–Cdk4 kinases. Phosphorylation and inactivation of RB1 enables E2F to bind DNA and transcribe genes required for S phase entry and cell proliferation. (b) p16INK4a expression is induced by hyper-proliferative signals from activated oncogenes or events during cellular aging that lead to *INK4a* derepression. Cdk4 binding by p16INK4a disrupts D1–Cdk4 association and leads to accumulation of hypophosphorylated RB1 and inactive E2F. Cells become reversibly arrested in G1 phase or undergo a permanent arrest termed senescence.

those events are compromised in human tumors. Summarizing over 20 years of research, studies show that the changing phosphorylation status of each cyclin and Cdk subunit plays an essential role in controlling their subcellular localization, stability, conformation, and binding to each other. Disrupting any of those controls can promote tumor formation by enhancing the activity of cyclin D- and E-dependent kinases. An additional level of negative control involves small proteins that bind and inhibit those kinases. These cyclin-dependent kinase inhibitors (CKIs) fall into two major classes, the Cip/Kip and INK4 proteins, and their in-depth characterization has been motivated by evidence that their inactivation occurs in a significant fraction of human cancers and promotes tumorigenesis (Malumbres and Barbacid, 2009).

The Cip/Kip family ('Cdk inhibitory' or 'Kinase inhibitory' proteins) includes p21Cip1 (*CDKN1A*), p27Kip1 (*CDKN1B*), and p57Kip2 (*CDKN1C*). Low levels of these proteins are actually critical for cyclin D-Cdk4/6 assembly and cell cycling, and their sequestration by D-Cdk4/6 complexes permits activation of the Cdk2 holoenzymes (Sherr and Roberts, 2004). However, their elevated expression strongly inhibits cyclin D-dependent kinases and halts cell proliferation, whereas even low concentrations of Cip/Kip proteins inhibit cyclin E-Cdk2 and A-Cdk2 as well as the M phase kinase, cyclin B-Cdk1. While Cip/Kip factors act broadly, the INK4 proteins selectively bind Cdk4 (or its homolog, Cdk6) and act as specific 'Inhibitors of Cdk4' (Figure 1(b)). The four members of the INK4 family (p16INK4a, p15INK4b, p18INK4c, and p19INK4d) were named based on their size (kDa) and order of discovery. These proteins are defined by the presence of four ankyrin repeats, which are required for their Cdk binding and inhibitory activity.

p16INK4a and RB1-Mediated Senescence

p16INK4a is the first identified, prototypical member of the INK4 family (Serrano *et al.*, 1993). p16INK4a and the other INK4 proteins each bind and inhibit Cdk4 (or Cdk6), and when expressed *in vivo* they primarily exist in binary INK4-Cdk complexes. Structural studies of p16INK4a and p18INK4c showed they function by blocking ATP binding and distorting the cyclin binding site in the Cdk, effectively preventing or disrupting the formation of cyclin D-Cdk4/6 holoenzymes (Jeffrey *et al.*, 2000; Russo *et al.*, 1998). In proliferating cells, the INK4 proteins are either absent (p16INK4a) or expressed at very low levels (e.g., p18INK4c). However, their expression is greatly increased in response to various cellular stresses or anti-proliferative signals, such as TGF- β , and their consequent inhibition of D-Cdk4/6 kinases potently arrests the cells in G1 phase. Importantly, the INK4 proteins have no growth inhibitory activity in cells that lack functional RB1, illustrating the strict linearity of the INK4-cyclin D-Cdk4/6-RB1 pathway (Sharpless and DePinho, 1999).

The primary differences between p16INK4a and its relatives occur in their tissue distribution, signals regulating their expression, and role in biology. For instance, p18INK4c and p19INK4d are normally induced by differentiation and expressed in non-proliferating cells within various tissues (e.g., spermatocytes in the testes and sensory hair cells in the

corti) (Zindy *et al.*, 1997; Krishnamurthy *et al.*, 2004). Their expression is vital for maintaining a quiescent state of differentiated cells, which has dire consequences when lost as indicated by the sterility of p18INK4c/p19INK4d-null male mice and deafness of p19INK4d-null animals (Zindy *et al.*, 2001; Chen *et al.*, 2003). By comparison, p16INK4a is undetectable in embryos and young mammals and becomes increasingly expressed in aging mice and humans (Zindy *et al.*, 1997; Krishnamurthy *et al.*, 2004; Ressler *et al.*, 2006). That expression pattern correlates with p16INK4a playing a role in cellular senescence, an irreversible cell cycle withdrawal associated with cell and organismal aging. Senescence is also important for tumor suppression, not only by promoting the permanent arrest of damaged cells but also by inducing their immune clearance (Xue *et al.*, 2007). p16INK4a is upregulated in cells undergoing senescence, induces telomere-independent senescence when expressed, and is required for senescence in cultured human cells (Darbro *et al.*, 2005; Collado *et al.*, 2007). Since loss of senescence is a key step in tumorigenesis, it is not surprising that *INK4a* gene inactivation is seen in nearly half of all human tumors (Ruas and Peters, 1998). While most of the INK4 and Cip/Kip proteins (except p19INK4d) have tumor suppressive activity, the frequency of *INK4a* inactivation in cancers far exceeds that of the other CKIs (Malumbres and Barbacid, 2009), suggesting a more prominent contribution of *INK4a* to tumor suppression.

INK4a/ARF – a Dual Coding Locus in Mammals

The role of *INK4a* in cancer became clouded by the startling realization that another transcript is encoded by the locus. Several groups made this discovery at the same time (Stone *et al.*, 1995; Mao *et al.*, 1995; Duro *et al.*, 1995; Quelle *et al.*, 1995), and while some thought the alternate transcript was noncoding it became clear that a protein was generated and it was a powerful cell cycle inhibitor in its own right (Quelle *et al.*, 1995). The locus is unusual because it encodes two unrelated proteins derived from separate first exons, exon 1 α for p16INK4a and exon 1 β for ARF, that are spliced to the same second exon (Figure 2). Each first exon supplies its own ATG start codon that initiates translation in alternative reading frames through shared sequences in exons 2 and 3, hence the name 'ARF' for the product of the β transcript. The resulting p16INK4a and ARF (mouse p19ARF, human p14ARF) proteins share no amino acid identity, and their structures and mechanisms of action are entirely distinct. While p16INK4a acts in the RB1 pathway, ARF activates the p53 tumor suppressor as well as other cancer pathways (Sherr, 2006; Kim and Sharpless, 2006; Gil and Peters, 2006), as described in following sections. This dual coding region was then renamed *INK4a/ARF* although the original locus designation, *CDKN2A* (which fails to convey the locus complexity), is still used prevalently in databases.

The *INK4a/ARF* locus is interesting from an evolutionary perspective. It is conserved in mammals, but chickens lack *INK4a* and only express a truncated ARF protein (p7) from an orthologous exon 1 β while neither *INK4a* nor *ARF* are found in fish (Gil and Peters, 2006). However, fish and chickens do retain an *INK4b* gene, which in the mammalian genome

Figure 2 Schematic of the *INK4a/ARF* locus. The *ARF* and *INK4a* genes, depicted with green and blue exons, respectively, span ~20 kb on human chromosome 9p21.3 or mouse chromosome 4. The α transcript for p16INK4a (blue) and β transcript for ARF (green) are generated from distinct promoters upstream of their first exons. Mouse and human ARF proteins differ in size due to C-terminal variations and are either 19 kDa (mouse) or 14 kDa (human). The *INK4b* gene (gray exons) encoding p15INK4b resides centromeric to exon 1 β of *ARF*. Intronic sequences are represented by the dashed black horizontal line. Representative exons (thought to total 19 and spanning ~120 kb) of the long noncoding RNA, *ANRIL* (also called *CDKN2BAS*), are depicted with red ovals and the transcript shown as a red arrow. *ANRIL* is transcribed in an antisense direction from a promoter element near that for exon 1 β of *ARF*. This image is not drawn to scale, but to give some perspective exon 1 β resides ~8 kb from p15INK4b exon 2 and ~13 kb from exon 1 α . Notably, this locus is a genomic hotspot for single nucleotide polymorphisms (SNPs) associated with several cancers and a variety of other age-related diseases in humans.

resides proximal to *ARF* exon 1 β (see Figure 2). Based on sequence analyses across species, it is thought that *INK4a* arose fairly recently in evolution by duplication of *INK4b* followed by subsequent acquisition of exon 1 β . The more recent appearance of ARF is consistent with the notion that dual coding allows for the expression of novel, intrinsically disordered proteins that perform new functions (Kovacs *et al.*, 2010). Indeed, p16INK4a has a well-defined α -helical structure and binds Cdk4/6 (Byeon *et al.*, 1998), while ARF is largely unstructured (especially in its C-terminal half derived from the alternative reading frame of exon 2) and participates in other pathways (Kovacs *et al.*, 2010; Sherr, 2006).

Dual coding of unrelated proteins from overlapping reading frames is typical in the compact genomes of prokaryotes and viruses, but it is rare in eukaryotes. For years, *INK4a/ARF* was thought to be the only genuine dual coding gene in mammals but other loci of biological importance have been identified. For instance, the XBP1^S transcription factor and its inhibitor, XBP1^U, arise from alternative reading frames in the *XBP1* (X-box binding protein 1) gene and their coordinated activity is required for such fundamental processes as plasma cell differentiation and the unfolded protein response (Yoshida *et al.*, 2001; Iwakoshi *et al.*, 2003). Likewise, *GNAS1* (G protein alpha subunit) encodes the unrelated G proteins, XL α s and ALEX, whose interaction is critical for multiple signaling pathways and whose loss of function is linked with several human disorders (Freson *et al.*, 2003; Turan and Bastepe, 2013; Klemke *et al.*, 2001). An intriguing theme is that the dual products perform related tasks, either by binding and regulating each other (e.g., *XBP1* and *GNAS1*) or by performing common functions (e.g., tumor suppression by *INK4a/ARF*). At least 40 additional dual coding genes, which have been dubbed hallmarks of fascinating biology, are thought to exist in eukaryotes (Kovacs *et al.*, 2010; Chung *et al.*, 2007).

***INK4a/ARF* – One Locus, Two Important Tumor Suppressors**

Chromosome 9p21 where *INK4a/ARF* resides is the second most frequently inactivated locus in human cancers (Ruas and Peters, 1998). Since their discovery, the relative role of

p16INK4a versus ARF in cancer has been a matter of intense investigation and debate. The cumulative data show that *INK4a* and *ARF* are most often co-inactivated by silencing or homozygous deletion of the entire locus, frequently including *INK4b*. In some cancers, such as glioblastoma, loss of *INK4a/ARF* is almost always achieved by gene deletion whereas in other tumor types, such as renal cell carcinomas, promoter methylation and silencing is the predominant mechanism (Figure 3). Inactivating mutations (nonsense, missense, and frameshift) of the locus are also common in certain cancers, especially sporadic and familial melanoma, as well as stomach and pancreatic adenocarcinomas. Notably, The Cancer Genome Atlas (TCGA) and other databases compile tumor data (copy number, mutation, methylation, RNA sequencing, etc.) for *CDKN2A*, which fails to distinguish between *INK4a*- and *ARF*-specific alterations unless data for each gene in each tumor are carefully examined. Such analyses reveal that ARF is selectively disabled in various cancers by alterations of exon 1 β or ARF's open reading frame in exon 2 (Ozenne *et al.*, 2010; Maggi *et al.*, 2014). Nonetheless, the vast majority of tumor mutations specifically target p16INK4a sequences in exons 1 α and 2 (Kim and Sharpless, 2006; Gil and Peters, 2006). This fostered a lingering perception that p16INK4a would play a larger role in cancer than ARF.

Specific disruption of exon 1 β or exon 1 α in mice conclusively showed that both ARF and p16INK4a are tumor suppressors (Kamijo *et al.*, 1997; Kamijo *et al.*, 1999; Sharpless *et al.*, 2001, 2004; Krimpenfort *et al.*, 2001). In fact, *ARF*-null mice develop spontaneous tumors with a slightly shorter latency than *INK4a*-null animals (Table 1). *ARF*-null mouse embryo fibroblasts (MEFs) also evade replicative and Ras oncogene-induced senescence, unlike MEFs lacking *INK4a*, indicating that ARF loss removes key checkpoints that normally prevent cell immortalization and transformation. The fact that p16INK4a loss had no effect on MEF senescence was perplexing given its apparent importance in human cell senescence (Kim and Sharpless, 2006; Campisi, 2005). An explanation was provided by studies of *INK4a/ARF* and *INK4a* knockout mice that lacked or retained *INK4b*, which showed p15INK4b is upregulated in the absence of p16INK4a and can compensate for its loss (Krimpenfort *et al.*, 2007). Redundancy among the INK4 proteins is also illustrated by the robust

Figure 3 Frequency of genetic alterations at the *CDKN2A* locus in selected human malignancies. The relative frequency of gene deletion, mutation, silencing, and amplification occurring at the *CDKN2A* locus harboring INK4a and ARF is displayed for various cancers. The percentage of tumors with silencing of the locus was calculated based on the difference between the percent of tumors showing reduced *CDKN2A* mRNA (primarily obtained from RNA-Seq data but also some microarray results) and those with gene deletion. A z-score threshold of $+/- 0.5$ was used to determine if *CDKN2A* mRNA expression was down-regulated. Separate data sources interrogating the same tumor type can display different types and frequencies of *CDKN2A* genetic inactivation (e.g., compare results from two separate sources for melanoma, pancreatic, or bladder cancers). Such variation may reflect differences in patient populations examined (number, ethnicity, etc.) or simply that some studies solely examine copy number aberrations (CNA data) or sequence level mutation data (Mutation data), as indicated, with or without accompanying mRNA data. This graphic is derived from multiple data sources (listed) including TCGA (The Cancer Genome Atlas) and was compiled with the aid of the cBioPortal (Gao *et al.*, 2013; Cerami *et al.*, 2012). NCI-60, cell line database compiled by the U.S. National Cancer Institute; CCLL, Cancer Cell Line Encyclopedia; MSKCC, Memorial Sloan Kettering Cancer Center; Broad, Broad Institute of MIT and Harvard; MICH, Michigan Center for Translational Pathology; ICGC, International Cancer Genome Consortium; GBM, glioblastoma multiforme; Adeno, adenocarcinoma; ACC, adenoid cystic carcinoma; and pRCC, papillary renal cell carcinoma.

tumor phenotype (and lack of MEF senescence) in mice expressing a Cdk4 mutant (R24C) that fails to bind all INK4 proteins and escapes their inhibition (Sotillo *et al.*, 2001a, b; Rane *et al.*, 2002). Thus, ARF and p16INK4a are important

regulators of cellular proliferation and senescence whose loss facilitates cancer.

Interestingly, tumor predisposition is enhanced in mice lacking both p16INK4a and ARF relative to the single

Table 1 Phenotypes of *ARF*, *INK4a*, and *INK4a/ARF* deficient or transgenic mice^a

Genotype	Alteration	Tumor phenotype	References
<i>INK4a/ARF</i> ^{-/-}	Exon 2 and 3 deletion	Sarcomas and lymphomas within 8.5 months; MEFs divide rapidly, are immortal and transformed by oncogenic Ras	Serrano <i>et al.</i> (1996)
<i>ARF</i> ^{-/-}	Exon 1 β deletion	Sarcomas, lymphomas, and carcinomas within 9.5 months; MEFs divide rapidly, are immortal and transformed by oncogenic Ras	Kamijo <i>et al.</i> (1997, 1999)
<i>INK4a</i> ^{-/-}	Exon 1 α deletion	Sarcomas and lymphomas within 11 months; increased T cell proliferation; MEFs senesce, not transformed by oncogenic Ras	Sharpless <i>et al.</i> (2001)
<i>INK4a</i> ^{mt/mt}	Knock-in of exon 2 point mutant ^b (encodes a defective p16INK4a protein)	Low incidence of spontaneous tumors (B-cell lymphoma) within 17 months; melanomas develop upon loss of one allele of <i>ARF</i> ; MEFs senesce and not transformed by oncogenic Ras	Krimpenfort <i>et al.</i> (2001)
<i>Cdk4</i> ^{R24C/R24C}	Knock-in of Cdk4 mutant insensitive to INK4 proteins ^b	Various tumors with complete penetrance, including invasive melanoma; MEFs immortal and easily transformed	Sotillo <i>et al.</i> (2001a, b), Rane <i>et al.</i> (2002)
<i>INK4b</i> ^{-/-} ; <i>INK4a</i> ^{mt/mt} ; <i>ARF</i> ^{-/-}	Deletion of exon 1 α , 1 β , and <i>INK4b</i> exons plus <i>INK4a</i> exon 2 point mutant ^b	More tumor prone and wider tumor spectrum than <i>INK4a/ARF</i> ^{-/-} mice; MEFs more sensitive to oncogenic transformation than <i>INK4a/ARF</i> ^{-/-} cells	Krimpenfort <i>et al.</i> (2007)
<i>ARF</i> ^{-/-} ; E μ -Myc	Exon 1 β deletion; Myc transgene in B cells	Accelerated B-cell lymphomagenesis relative to E μ -Myc mice ^c ; mice die by 7 weeks of age versus 6 months in E μ -Myc mice	Eischen <i>et al.</i> (1999)
<i>INK4a/ARF</i> ^{-/-} ; Tyr-Ras ^{G12V}	Exon 2/3 deletion; mutant KRas in melanocytes	Cutaneous melanoma with short latency and high penetrance	Chin <i>et al.</i> (1997)
<i>ARF</i> ^{-/-} ; <i>p53</i> ^{-/-} ; <i>Mdm2</i> ^{-/-}	Triple knockout of <i>ARF</i> exon 1 β , <i>p53</i> and <i>Mdm2</i>	Much broader spectrum of tumors, and multiple tumors per animal, compared to mice lacking <i>ARF</i> or <i>p53</i> alone	Weber <i>et al.</i> (2000)
<i>ARF</i> ^{-/-} ; RIP-Tag	Exon 1 β deletion; SV40 T antigen expression in β cells	Accelerated formation of pancreatic neuroendocrine tumors with increased angiogenesis relative to RIP-Tag mice	Ulanet and Hanahan (2010)
<i>Pdx1-Cre</i> ; <i>KRas</i> ^{G12D} ; <i>INK4a/ARF</i> ^{fllox/fllox}	Tissue-specific expression of mutant KRas and <i>INK4a/ARF</i> exon 2/3 deletion	Accelerated development of pancreatic intraepithelial neoplasias (PanINs); metastatic pancreatic ductal adenocarcinoma (PDAC) and death by 2–3 months of age	Aguirre <i>et al.</i> (2003)
<i>ARF</i> ^{-/-} or <i>INK4a</i> ^{-/-} on <i>Ntv-a</i> or <i>Gtv-a</i> background	Neural- or astrocyte-specific expression of PDGFB in exon 1 β or 1 α deleted mice	Development of PDGFB-induced gliomas; much greater incidence of high-grade tumors in <i>ARF</i> ^{-/-} mice than <i>INK4a</i> ^{-/-} mice	Tchougounova <i>et al.</i> (2007)
<i>INK4/ARF</i> -tg	One extra allele of <i>INK4b-ARF-INK4a</i>	Increased cancer resistance, reduced production of sperm, normal aging	Matheu <i>et al.</i> (2004)
<i>INK4/ARF</i> -tg/tg	Two extra alleles of <i>INK4b-ARF-INK4a</i>	Further enhanced cancer resistance, absence of sperm, decrease in aging markers, and extended longevity	Matheu <i>et al.</i> (2009)

^aIncomplete listing of mouse models with altered *INK4a* and *ARF*.^bNaturally occurring point mutations found in human tumors, including melanomas.^cLoss of *INK4a* or *RB1* does not accelerate E μ -Myc lymphomagenesis (Lowe and Sherr, 2003).

knockout animals (Sharpless *et al.*, 2004; Serrano *et al.*, 1996). The synergism of dual p16INK4a and ARF loss on mouse tumorigenesis is consistent with the distinct molecular functions of each protein and with human clinical data showing their frequent co-inactivation. Still, it was disappointing that mice lacking ARF, p16INK4a, or both factors did not frequently develop the types of cancer commonly seen in humans bearing *INK4a/ARF* alterations (e.g., melanoma, glioblastoma, and pancreatic adenocarcinoma). Most mice lacking ARF and/or p16INK4a develop sarcomas or

lymphomas. It is widely appreciated that human tumors sustain multiple genetic changes concomitant with *INK4a/ARF* loss (Hanahan and Weinberg, 2011). Therefore, many studies have since tested the cooperative effects of *INK4a* and/or *ARF* loss when coupled with oncogene activation (e.g., Ras or Myc) or tumor suppressor inactivation (e.g., p53) (see Table 1). Such compound mouse mutants successfully model the tumor types seen in humans and demonstrate a critical role for p16INK4a and/or ARF inactivation in those cancers. Conversely, 'super-*INK4a/ARF*' mice expressing one or

two extra alleles of the *INK4a/ARF/INK4b* locus display a dose-dependent resistance to cancer (Matheu *et al.*, 2007, 2009).

ARF, a Multi-Faceted Tumor Suppressor

Unlike p16INK4a, which has one target (Cdk4/6) and acts within a single pathway, ARF binds to many proteins and regulates numerous cancer pathways (Figure 4), as reviewed in (Sherr, 2006; Ozenne *et al.*, 2010; Maggi *et al.*, 2014; Gil and Peters, 2006). The dominant mechanism by which ARF prevents cancer is through activation of p53. Widely considered the 'guardian of the genome,' p53 is the most commonly inactivated tumor suppressor gene in human cancers (Levine and Oren, 2009; Vousden and Prives, 2009). As a transcription factor, p53 regulates over a hundred genes involved in cell proliferation, survival, senescence, metabolism, and migration, among other processes in response to cellular stress. In so doing, p53 activates checkpoints that protect cells from hypoxia, telomere attrition, oncogene activation, DNA damage, and other insults that threaten the genome. It is normally kept at low levels in cells by Mdm2, an E3 ubiquitin ligase and p53 transcriptional target that promotes p53 ubiquitination and degradation (Senturk and Manfredi, 2012). Mdm2 can also block p53 transactivation and facilitate its translocation out of the nucleus. ARF inhibits Mdm2 and disrupts the Mdm2–p53 negative feedback loop, thereby stabilizing and activating p53. It does so by binding Mdm2 in either the nucleoplasm or nucleoli, physically sequestering Mdm2 away from p53 while also antagonizing Mdm2 ubiquitin ligase activity. As a result, ARF potently stimulates p53-dependent transcription and growth inhibition.

Figure 4 The ARF anti-proliferative pathways. ARF expression is induced by aberrant hyper-proliferative signals elicited by activated oncogenes or events during cellular aging, including DNA damage, that lead to *INK4a/ARF* derepression. Once expressed, ARF activates p53-mediated transcription through its inhibition of Mdm2. ARF also binds numerous proteins independently of p53 and consequently regulates many other cancer pathways. Through both p53-dependent and p53-independent mechanisms, ARF promotes senescence, cell cycle arrest, apoptosis, and DNA repair, among other antitumor activities, thereby helping to preserve genomic integrity.

Early models suggested that ARF acted solely through p53 to suppress cancer. This was based on initial studies suggesting mutually exclusive loss of ARF or p53 in human tumors, as well as observations that ARF caused robust cell cycle arrest and death in p53-positive (but not p53-negative) cells. However, many studies over the years have shown that ARF retains substantial tumor suppressive activity in the absence of p53 (Sherr, 2006; Ozenne *et al.*, 2010; Maggi *et al.*, 2014). Specifically, ARF expression can cause delayed apoptosis, cell cycle arrest or senescence in cells with nonfunctional p53. It can also inhibit ribosome biogenesis, reduce tumor cell migration and angiogenesis, activate pathways that repair damaged DNA, and promote autophagy ('self-eating'). For the latter, full-length ARF and a short mitochondrial ARF (smARF; translated from an internal methionine) isoform have been shown to localize to mitochondria and induce autophagy in a p53- and caspase-independent manner (Balaburski *et al.*, 2010). Collectively, these p53-independent activities of ARF reflect its binding to numerous proteins besides Mdm2. Approximately 40 ARF partners have been identified to date (Figure 4).

There is still much to learn about the biological significance of ARF's many interactions. Nevertheless, the diversity of ARF binding proteins underscores the breadth of ARF's p53-dependent and p53-independent tumor suppressive activities (Sherr, 2006; Maggi *et al.*, 2014; Ozenne *et al.*, 2010). ARF associates with transcriptional activators (e.g., Myc, HIF1α, FoxM1b, E2F1, DP1, YY1, p53, and p63), transcriptional repressors (e.g., E2F4, BCL6, CtBP1/2), checkpoint kinases (e.g., ATM and ATR), ligases involved in ubiquitination or sumoylation (e.g., Mdm2, ARF-BP1, and UBC9), factors controlling ribosomal RNA and DNA synthesis (e.g., NPM, nucleolin, TTF-1, DDX5, and UBF), DNA modifying enzymes (e.g., WRN and Topoisomerase I (TopoI)), acetyltransferases (e.g., Tip60), and viral proteins (e.g., TBP1 and human papilloma virus (HPV) 16 E7), among other proteins. Many of those partners are oncogenic proteins, such as Myc and FoxM1b, whose tumor-promoting activities are inhibited by ARF. Other partners suppress cancer (e.g., Tip60 and ATM) and are activated by ARF as part of checkpoints that protect against hyper-proliferative signaling (i.e., oncogene activation) or DNA damage.

Notably, cooperative effects of ARF's p53-dependent and p53-independent activities are expected since many ARF partners affect p53 signaling while also influencing other cellular processes separate from p53. Mdm2 and its relative, MdmX (also called Mdm4), for example, both inhibit p53 yet can also function independently of p53 in the DNA damage response to impede DNA repair and increase genome instability (Melo and Eischen, 2012; Senturk and Manfredi, 2012). Similarly, NIAM is a 'nuclear interactor of ARF and Mdm2' that is able to activate p53 through inhibition of Mdm2 (Reed *et al.*, 2014a), yet it also acts through undefined mechanisms to suppress proliferation and promote chromosomal stability in the absence of p53 (Tompkins *et al.*, 2007). Perhaps the best example is nucleophosmin (NPM1), one of the better validated ARF interacting proteins (Grisendi *et al.*, 2006). NPM1 is an abundant nucleolar phosphoprotein that inhibits ARF-mediated p53 activation by retaining ARF in nucleoli and blocking its sequestration of Mdm2 away from p53. Independently of p53, NPM1 is also required for ARF stability and nucleolar

localization (where most ARF protein resides) while ARF upregulation blocks NPM1 nucleocytoplasmic shuttling, thereby interfering with ribosome nuclear export (Sherr, 2006; Maggi *et al.*, 2014). ARF–NPM1 co-regulation therefore impacts p53 signaling as well as other pathways affecting ribosome function and cell proliferation.

The physiological importance of ARF's many p53-independent activities has been demonstrated by the striking phenotypes of mouse tumor models specifically lacking ARF on a p53-deficient background (see Table 1). The first realization that ARF suppresses cancer in living animals independent of p53 came from a seminal study showing that *ARF/Mdm2/p53* triple knockout mice develop a wider range of tumor types and multiple primary tumors per animal relative to *ARF*^{-/-}, *p53*^{-/-} or *Mdm2/p53*^{-/-} mice (Weber *et al.*, 2000). Others showed that ARF (but not p53) is required for oncogene-induced senescence in benign nevi, and its loss combined with N-Ras activation promotes melanocyte transformation and melanoma development (Ha *et al.*, 2007). In a mouse model of pancreatic neuroendocrine tumors in which p53 and RB1 are both inactivated by the SV40 large T antigen, ARF deficiency accelerates tumor formation by promoting tumor angiogenesis (Ulanet and Hanahan, 2010). These *in vivo* studies exemplify how ARF can suppress cancer independent of p53 through multiple mechanisms, such as promoting senescence in benign neoplasias and inhibiting blood vessel formation within existing tumors.

Regulation and Loss of *INK4a/ARF* in Cancer

Genetic inactivation of *INK4a/ARF* is a frequent event in tumor development, observed in nearly half of all human malignancies. However, functional loss of p16INK4a and/or ARF in tumors can be achieved through a variety of other mechanisms

including enhanced promoter methylation and silencing, loss of transcriptional activators, reduced translation, increased protein degradation, and altered expression of their target/effector proteins (Figure 5). In fact, alterations of *INK4a/ARF* or its regulators and effector pathways are thought to occur in essentially all human cancers. In many cases, the entire locus is lost by genetic deletion or coordinated transcriptional repression; however, the separate control of *INK4a* and *ARF* by unique factors or signals reveals how a significant number of tumors with an intact *INK4a/ARF* locus may lack ARF function while retaining p16INK4a activity (or vice versa).

In normal cells, *INK4a/ARF* is tightly silenced by chromatin-associated Polycomb repressive complexes (PRC1 and PRC2) and histone deacetylase (HDAC) complexes (Gil and Peters, 2006; Kim and Sharpless, 2006; Aguilo *et al.*, 2011). This is important for normal cell proliferation, stem cell self-renewal, and tissue homeostasis since aberrant derepression of *INK4a/ARF* (as seen in mouse knockouts lacking PRC components Bmi1, CBX7 or EZH2) causes significant hematological, pancreatic, and neurological defects. PRC recruitment to *INK4a/ARF* is mediated by binding of the Polycomb group protein, CBX7, to the long noncoding antisense RNA *ANRIL* (Yap *et al.*, 2010), which spans the *INK4b/INK4a/ARF* locus (see Figure 2). As normal cells senesce or encounter stresses that induce senescence, such as oncogene activation or DNA damage, the expression of *ANRIL* and *EZH2* declines leading to displacement of the repressive complexes and activated transcription of *INK4a/ARF*. The consequent induction of p16INK4a and ARF signaling provides a powerful defense against cellular transformation and tumor progression. In cancer cells, however, the levels of *ANRIL*, CBX7, and other PRC components can be elevated causing improper maintenance of *INK4a/ARF* repression.

Induction of *INK4a/ARF* is principally stimulated by hyperproliferative signals emanating from activated oncogenes, such

Figure 5 Multiple targets for disruption of p16INK4a and ARF function in human cancers. In normal cells, the *INK4a/ARF* locus is tightly silenced by repressive complexes containing Polycomb group (PcG) proteins, such as Bmi1, CBX7, and EZH2. Derepression of the locus is induced by hyper-proliferative signals emitted by activated oncogenes, such as Ras or Myc. This leads to p16INK4a and ARF expression, activation of their respective tumor suppressor pathways, and induction of senescence or apoptosis (acute response) or reduced cell proliferation, DNA repair, migration, metabolism, etc. Most cells maintain this ‘inhibited state.’ However, the few cells that escape those constraints can do so through a variety of mechanisms: (1) genetic deletion or mutation of *INK4a/ARF*, (2) promoter silencing due to upregulation of factors in the PcG repressive complexes and DNA hyper-methylation, (3) loss of key activators (e.g., the DMP-1 transcription factor for ARF) or effectors (e.g., RB1 for p16INK4a or p53 for ARF), and (4) hyper-activation of oncogenic target proteins (examples are bolded). An incomplete listing of negative and positive regulators of *INK4a/ARF* is shown, with specific regulators of ARF (*) and p16INK4a (#) indicated.

as Ras or Myc, thereby engaging RB1, p53, and ARF/p53-independent checkpoints that protect against unrestrained cell proliferation, genomic mutation, and cancer (Kim and Sharpless, 2006; Gil and Peters, 2006; Ozenne *et al.*, 2010; Sherr, 2012). For the most part, oncogenic stress causes the coordinated upregulation of both p16INK4a and ARF by transcriptional activators, such as E2F1. The role of *INK4a/ARF* in DNA damage checkpoints is less clear and more controversial. Various types of DNA damage induce p16INK4a, ARF, or both proteins; however, their upregulation is generally delayed and may be more important for mediating long-term responses (including DNA repair or senescence) following chronic and/or low-level DNA damage as opposed to acute DNA damage. Consistent with that notion, ARF was found to be required for p53-dependent tumor suppressive activities in irradiated mice once the acute, pathological response to DNA damage had ended (Christophorou *et al.*, 2006).

While *INK4a* and *ARF* are often co-regulated, a large number of factors selectively regulate the individual genes or transcripts. Several *INK4a*-specific transcriptional activators (e.g., JunB, Ets1/2) and repressors (e.g., Id1, Id3) have been identified, as have *ARF*-specific transcriptional activators (e.g., DMP-1, AML1) and repressors (e.g., Twist, AML-ETO). At the posttranscriptional level, the RNA binding protein HuR (which is upregulated in various cancers and inhibits senescence) negatively regulates *INK4a* and *ARF* mRNAs but through distinct mechanisms that depend on cell context (Maggi and Weber, 2013). In human diploid fibroblasts, HuR binds and destabilizes the *INK4a* mRNA whereas in MEFs it binds the 5' UTR of the *ARF* mRNA and blocks its translation by preventing nucleolin-*ARF* mRNA association and export to the cytoplasm. The basis for differential HuR regulation of *INK4a* and *ARF* in mouse and human cells is unclear, but it is not entirely unusual since Ras activation selectively induces p16INK4a in human cells despite upregulating both p16INK4a and ARF in rodent cells (Gil and Peters, 2006; Kim and Sharpless, 2006).

Other mechanisms distinctly controlling ARF or p16INK4a may play an important role in cancer. UFL, an 'ubiquitin ligase for ARF,' is upregulated in tumors and lowers ARF levels by promoting its lysine-independent ubiquitination and proteasomal degradation (Chen *et al.*, 2010). Intriguingly, ARF can promote p16INK4a degradation via its interaction with the REG γ subunit of the proteasome (Kobayashi *et al.*, 2013). Such crosstalk between the *INK4a/ARF* products may constitute an autoregulatory feedback loop to reduce p16INK4a levels, enabling cell cycle reentry following a successful checkpoint response and thereby delaying aging (see below). ARF is also subject to negative feedback regulation but it occurs at the transcriptional level due to p53-mediated repression. Specifically, ARF is induced by activated oncogenes and activates p53; subsequently, p53 binds the promoter for *ARF* (not *INK4a*) and recruits HDACs and Polycomb group proteins to repress its transcription (Robertson and Jones, 1998; Zeng *et al.*, 2011). Those results explain why cancer cells lacking p53 often express high levels of ARF.

Increased expression of ARF in cells lacking p53 is a beneficial barrier against tumorigenesis due to its many p53-independent activities, as discussed earlier. This was effectively illustrated in a recent study that showed ARF upregulation

following acute p53 loss inhibits interferon β (IFN- β) production and signaling, markedly restricting the proliferation and tumorigenicity of those cells (Forys *et al.*, 2014). Unfortunately, there is strong selective pressure for cells to escape such constraints and remove ARF to enable proliferation, facilitating the outgrowth of tumor cells with activated IFN- β signaling. In fact, analyses of human triple-negative breast cancer samples revealed that more than 50% have co-inactivation of ARF and p53 as well as hyperactive IFN signaling. Those findings may be useful in the clinic since they suggest that therapies targeting IFN- β effectors, such as STAT1, would be appropriate for treating tumors with combined p53 and ARF inactivation.

INK4a/ARF in Aging

Genome-wide association studies (GWAS) in millions of patients implicate the *INK4a/ARF* locus in a range of aging-related diseases (Jeck *et al.*, 2012). The data identify a hotspot of single nucleotide polymorphisms (SNPs) on chromosome 9p21.3 spanning the *INK4a/ARF* locus (and the sequences encoding p15INK4b and *ANRIL*) that is associated with increased risk for type 2 diabetes, glaucoma, late onset Alzheimer's, frailty, and atherosclerotic pathologies including stroke, myocardial infarction, and aortic aneurysm (see Figure 2). Exactly how the different SNPs affect *ANRIL* and *INK4a/ARF* expression, however, is not well understood. Some SNPs associated with a higher risk of atherosclerosis increase the expression of *ANRIL* isoforms and circular species, thereby enhancing repression of *INK4a/ARF* in peripheral blood T cells and causing reduced p15INK4b, p16INK4a, and ARF levels (Burd *et al.*, 2010). Other SNPs may reduce *ANRIL* expression, which would be predicted to increase p16INK4a and ARF levels. That seems likely for SNPs associated with type 2 diabetes since precocious expression of p16INK4a and ARF in pancreatic β cells of *EZH2*-null mice impairs β cell proliferation, reduces insulin production, and promotes type 2 diabetes (Chen *et al.*, 2009). Rescue of those defects by *INK4a/ARF* deletion established a causative role for p16INK4a and/or ARF in that process.

The observations above suggest that loss and gain of *INK4a/ARF* expression can each promote aging phenotypes, so does the locus accelerate or delay aging? The answer is complicated and still unfolding. On the one hand, substantial evidence suggests *INK4a/ARF* enhances aging (reviewed in Sorrentino *et al.*, 2014; Sherr, 2012). This includes findings that p16INK4a and ARF levels increase in aging mouse and human tissues, promote cellular senescence (which accumulates with organismal aging), and are regulated by age-modifying stimuli such as caloric restriction. Also, elevated p16INK4a and ARF levels have been linked to the age-dependent decline in normal stem cell function in the neural, pancreatic, muscle, and hematopoietic stem cell compartments. On the other hand, transgenic mice expressing two extra copies of the *INK4b/ARF/INK4a* locus (*INK4/ARF*-tg/tg) have reduced signs of aging and a longer life span, with the delayed aging phenotype distinct from the reduced cancer incidence seen in those animals (Matheu *et al.*, 2009). How can such apparently contradictory findings be reconciled?

One explanation is that p16INK4a and ARF have separate, opposing roles in aging and that the pro-aging effects of p16INK4a may be countered by antiaging activities of ARF. For instance, p16INK4a (not ARF) expression is increased in aging T-cell progenitors, significantly reduces their number and promotes thymic involution (Berent-Maoz *et al.*, 2012), a well-recognized change in the elderly linked with impaired immunity. Also, selective ablation of *INK4a* or *ARF* in a progeroid mouse model of premature aging (*BubR1*-deficient mice) showed that p16INK4a promotes senescence and aging, whereas ARF suppresses those processes (Baker *et al.*, 2008, 2011). The antiaging effect of ARF in this setting may be partly mediated through negative regulation of p16INK4a levels since *ARF* deletion increases p16INK4a expression in tissues displaying accelerated aging (muscle, fat, and eye). ARF may also protect against aging by inducing a p53 transcriptional response involving antioxidant gene expression which promotes quiescence, DNA repair, and cell survival. The fact that p53 loss phenocopies ARF loss in *BubR1* mutant mice supports that notion (Baker *et al.*, 2008), as does the upregulation of antioxidant p53 targets and delayed aging of *ARF/p53* transgenic mice (Matheu *et al.*, 2007).

It is also possible that both *INK4a* and *ARF* have antiaging effects although the timing and context of their expression may be important. Although acute *INK4a/ARF* upregulation during oncogenesis may cause excessive cell apoptosis or senescence that compromises tissue integrity and accelerates aging, the progressive low-level activation of the locus during aging could be beneficial by slowing cell proliferation rates or triggering a reversible quiescent arrest, thereby delaying the exhaustion of stem cell pools (Matheu *et al.*, 2009). The mitochondrial smARF form of ARF may also inhibit aging. Studies in neurons showed that smARF is a critical upstream activator of a Parkin/PINK1 mitophagy pathway that eliminates damaged mitochondria from cells (Grenier *et al.*, 2014). This is relevant because impaired Parkin/PINK1-mediated mitophagy in neurons is thought to cause the accumulation of damaged mitochondria that occurs during aging and is associated with Parkinson's disease (PD). Whether or not smARF levels and activity are impaired in PD brains and how this pathway contributes to neurodegeneration in PD remains to be determined. Indeed, more work is needed to define the individual and combined roles of p16INK4a, ARF, and smARF in aging and age-related disorders. Nonetheless, the cumulative evidence establishes that *INK4a/ARF* is a bona fide aging locus.

Unique Roles of ARF in Development

INK4a/ARF repression is necessary and widespread throughout most tissues during development. However, there are a few cell types where transient ARF expression is critical for proper development, particularly in the eye and testes (Gromley *et al.*, 2009). *ARF*-null mice are blind with smaller eyes than *ARF*-positive animals, mimicking a human eye disease called persistent hyperplastic primary vitreous (PHPV) (McKeller *et al.*, 2002). The blindness results from elevated expression of platelet-derived growth factor receptor β (PDGFR β) in perivascular cells within the vitreous of the eye, which causes their

aberrant proliferation and prevents the regression of the hyaloid vascular system required for proper retina and lens formation (Reed *et al.*, 2014b). At the molecular level, ARF suppresses PDGFR β expression through complementary mechanisms that are p53-dependent (repression of PDGFR β transcription) and p53-independent (upregulation of the miR-34a microRNA and inhibition of PDGFR β translation).

Paradoxically, ARF expression in male germ cells has no effect on proliferation and instead promotes the survival of spermatogonia by blocking p53-mediated apoptosis, contrasting with its role as a p53 activator in cancer (Churchman *et al.*, 2011). *INK4a*-null mice do not display developmental defects. However, it is notable that overexpression of p16INK4a, p15INK4b, and ARF in transgenic *INK4/ARF*-tg/tg mice causes male sterility (see Table 1; Matheu *et al.*, 2009). This is thought to reflect a proliferative defect of the spermatogonia due to increased *INK4a/b*-RB1 mediated growth inhibition rather than ARF-p53 effects.

Conclusions

In summary, ARF and p16INK4a are major barriers to the outgrowth of cancer cells. Their induction by various cell stresses, particularly hyper-proliferative stimuli and aging signals, and consequent activation of the p53 and RB1 tumor suppressors is critical for their anticancer function. In the absence of p53, ARF can also function through many other pathways to induce senescence and suppress tumor cell survival, migration, angiogenesis, etc. Through those pathways, each protein engages protective checkpoints that inhibit cancer cell outgrowth by reversible cell cycle arrest (and DNA repair) of mildly damaged cells or irreversible removal of severely damaged cells via senescence or apoptosis, thereby ensuring genomic integrity.

The importance of these pathways in human cancer is demonstrated by their frequent disruption in tumors. Indeed, functional inactivation of p16INK4a, ARF, p53, and/or RB1 is thought to occur in most, if not all, human tumors due to genetic/epigenetic inactivation and alterations targeting their signaling pathways (Figure 5). Advancing our understanding of these pathways and employing that knowledge to improve tumor diagnosis, prognosis, and treatment is the ultimate goal. For example, preclinical studies suggest that ARF peptides targeting the FoxM1b oncogenic protein have beneficial anti-tumor activity in mouse models of lymphoma and sarcoma (Wang *et al.*, 2013). Selective inhibitors of Cdk4/6 are further along in development and show significant clinical promise in treating RB1-positive tumors that lack functional p16INK4a (Flaherty *et al.*, 2012).

Derepression of the *INK4a/ARF* locus is also important in cellular and organismal aging although its impact on age-related pathologies and longevity is complex. Whether or not *INK4a/ARF* is a benefit or liability to aging is controversial and still under investigation. The context (timing, level, cause, and tissue) of *INK4a/ARF* regulation and whether p16INK4a, ARF or both proteins are expressed may be critical in dictating outcome. That said, the fact that increased *INK4/ARF* gene dosage in mice leads to delayed aging and an extended life span (as well as increased cancer resistance) makes a

persuasive case that more *INK4a/ARF* is better, at least if you are a mouse (and female, since the male transgenic mice are sterile). For humans, any potential benefit of manipulating *INK4a/ARF* to prolong life (beyond the protection against cancer) requires a firmer grasp on how, when, and where p16^{INK4a} and/or ARF expression influences the aging process.

S Phase

SJ Smith, RG Lingeman, CM Li, L Gu, RJ Hickey, and LH Malkas, Beckman Research Institute at City of Hope, Duarte, CA, USA

Introduction

The S (synthesis) phase occurs between the G1 and G2 phases of the cell cycle. It is during this phase that the genomic DNA within the nucleus is replicated. The steps involved in faithfully executing the duplication of the genomic information of the cell include: signaling the G1 to S phase transition, replicating both DNA strands, and repairing DNA damage prior to the G2 phase.

S Phase Activation

Cyclin-Dependent Kinases

The transition from G1 to S phase is controlled by the interaction of cyclin-dependent kinases (CDKs). Prior to the initiation of cell division, CDK4 and CDK6 are inhibited by p16 (a CDK inhibitor). Upregulation of cyclin D expression displaces p16 binding to CDKs, thereby activating the CDKs. Activated CDK4 and CDK6 are then able to phosphorylate and inactivate retinoblastoma (Rb) protein, subsequently activating E2F transcription factors which ultimately initiate DNA replication. Progress has been made in understanding how CDK-phosphorylated substrates can elicit origin firing. Through the study of budding yeast, it has been demonstrated that replication origin firing requires two essential CDK targets, Sld2 and Sld3. Sld3 must be phosphorylated to bind DpbII (TopBP1 orthologue), while phosphorylated Sld2 promotes DpbII binding. This trimeric complex acts as a docking platform for other proteins required in the assembly and firing of replication origins (Tanaka *et al.*, 2007; Zegerman and Diffley, 2007).

In contrast, the CDK inhibitor, p27, inhibits CDK2 and CDK4 activities and arrests the cell cycle prior to entry into the S phase. The involvement of a network of cellular components enables cells to respond to various intracellular and extracellular conditions and integrate these input signals to determine the initiation of DNA replication.

Myc Control

Myc, a transcription factor encoded by the MYC proto-oncogene, is a key regulator of G1–S progression and plays a direct role in the control of DNA replication. Myc is broadly expressed during embryogenesis, but it is also expressed in highly proliferative adult tissues (epidermis and gut) (Spencer and Groudine, 1991). Enforced expression of Myc is sufficient to stimulate quiescent cells to proliferate (Eilers *et al.*, 1991), and dysregulation of Myc expression has been found in about 50% of all solid tumors (Nesbit *et al.*, 1999). Therefore, physiological and pathological expression of Myc closely correlates to the proliferative status of cells. Structurally, Myc belongs to the helix–loop–helix/leucine zipper protein family.

It binds to the DNA consensus sequences of the E-box (enhancer box) in complex with Max proteins and activates transcription by recruiting transcriptional coactivators to its target genes (Blackwood and Eisenman, 1991). Myc target genes include CCND2, which encodes cyclin D2, CDK4, CUL1, and CKS (Pelengaris *et al.*, 2002). Together, the proteins encoded by these genes are responsible for the sequestration of CDK inhibitor p27 in cyclin-D2–CDK4 complexes and the subsequent degradation of p27 (O'Hagan *et al.*, 2000), thereby allowing activation of the cyclin-E–CDK2 complex. In addition to activating genes involved in cell cycle progression, the MYC–MAX heterodimers can repress the expression of CDK inhibitors, such as INK4B and WAF1/p21, by interacting with transcription factors MIZ1 and/or SP1 (Brenner *et al.*, 2005; Gartel *et al.*, 2001). By activating or repressing its target genes, Myc plays a critical role in activating CDKs and promoting G1–S progression.

DNA Replication

During the S phase of the cell cycle, DNA must be replicated error-free to ensure the correct genomic information is transferred to the newly created cells. In order to successfully complete this process, specific proteins and enzymes must coordinately activate. As cells increase in complexity (from bacteria to mammals), the process of DNA replication becomes more elaborate. However, the basic mechanism for each cell type is similar. Numerous biochemical and genetic studies have revealed the basic mechanisms involved in this semi-conserved process. The replication of double-stranded DNA (dsDNA) involves the coordination of a helicase for DNA unwinding, the protection of the single-strand with DNA-binding proteins, and synthesis involving clamp loaders, polymerases, a DNA ligase, and DNA topoisomerases.

Replication Fork Formation

Upon the initiation of DNA replication, the helical dsDNA must be unwound and separated into two separate parental strands that act as a template for replication. This step is accomplished with the help of a ring-shaped structure that contains a nucleotide-binding (AAA+) domain, often referred to as a helicase. The most commonly characterized of these is DnaB from *Escherichia coli*. This homohexamer possesses the ability to self-load onto single-strand DNA (ssDNA), and is large enough to fit dsDNA through to unwind it. The helicases of archaea and eukaryotes, however, are composed of minichromosome maintenance (MCM) proteins. While most archaeal helicases consist of one MCM protein, most eukaryotes have helicases consisting of six distinct MCM proteins, Mcm2–7.

What is unique to these higher order cells is the MCM helicases cannot unwind the DNA strands alone. Once the

origin replication complex (ORC) is activated, Cdc6 and Cdt1 are signaled, which in turn load Mcm2-7, followed by helicase activation (Cdc45–Mcm2-7–GINS (CMG) complex) (Tanaka and Araki, 2010). Mammalian helicases exhibit features structurally distinct from bacterial helicases: the N-terminal domains of Mcm2-7 are structurally unrelated to DnaB, and the C-terminal motor domain of Mcm is an AAA+ protein, which is evolutionarily and organizationally distinct from DnaB with its RecA-type motors (Costa *et al.*, 2013). Single-particle electron microscopy (EM) reconstructions of *Drosophila melanogaster* reveal that the Mcm2-7 relies on the weak Mcm2–Mcm5 interaction to spontaneously open up the hexamer (Costa *et al.*, 2011). For each ORC–Cdc6 interaction, Mcm2-7 is loaded as a double hexamer in a head-to-head configuration on the dsDNA (Costa *et al.*, 2013). Eukaryotes will use an AAA+ -type initiator similar to that observed in bacteria in order to catalyze the DNA loading. GINS and Cdc45 form a complex with Mcm2-7, significantly increasing adenosine triphosphatase (ATPase) activity, allowing for 3'→5' DNA unwinding (Costa *et al.*, 2011). The CMG complex is thought to directly promote duplex opening and strand separation by splitting the dsDNA between the pore of the helicase and the pore formed by GINS–Cdc45–Mcm235 (Costa *et al.*, 2011).

The Replication Fork

The separation of dsDNA results in the formation of a Y-shaped junction, which is more commonly referred to as the replication fork. Single-strand binding (SSB) proteins protect the exposed ssDNA from premature annealing and nuclease digestion. Most SSB proteins contain at least one conserved DNA-binding oligonucleotide/oligosaccharide binding (OB) fold. These folds can range from 70 to 150 amino acids in length, forming β -barrels capped with an α -helix (Marceau, 2012). Most eukaryotic cells use replication protein A (RPA) as the SSB protein. RPAs form heterotrimers (RPA70, RPA34, RPA14), while most bacterial SSB proteins form homotetramers. Archaeal SSBs resemble either bacterial SSBs or eukaryotic RPAs.

DNA is replicated in a manner that results in a leading strand synthesized continuously and a lagging strand synthesized discontinuously. The leading-strand DNA is processed by a polymerase in the same direction of helicase unwinding, while the lagging strand is synthesized in the opposite direction. The most thoroughly characterized model, *E. coli*, utilizes the DNA polymerase III holoenzyme and other essential proteins, including the DnaB helicase and DnaG primase (Baranska *et al.*, 2013). The most commonly used model for eukaryotic systems is *Schizosaccharomyces pombe* (Aves *et al.*, 2012).

Leading-strand synthesis

At the leading strand, SSB proteins help to load and stabilize the DNA pol α -primase complex (Dornreiter *et al.*, 1992). The pol α -primase synthesizes an RNA primer using complementary base pairing to associate with ssDNA. Following primer synthesis, replication factor C (RFC) competitively binds RPA to disrupt the pol α interaction and load proliferating cell

nuclear antigen (PCNA) (Waga and Stillman, 1998). PCNA is a 29 kDa protein that forms a homotrimer to encircle the DNA strand, thus acting as a loading scaffold for other proteins and enzymes within the replication process, such as DNA polymerase δ and ϵ (Burgers, 1988). PCNA/RPA function to tether the replicative polymerase pol δ to the DNA, thereby acting as a 'polymerase switch' to replace the primase with polymerase, which further processes the new strand of DNA (Forsburg, 2008; Trujillo and Osley, 2008). With the polymerase tethered to the DNA, the leading strand is synthesized in long, continuous segments in the 5'→3' direction.

Lagging-strand synthesis

Owing to the antiparallel nature of DNA replication, the lagging strand is synthesized in a much different manner than the leading strand. The lagging strand is synthesized discontinuously in short segments growing away from the replication fork. These segments are called Okazaki fragments (Rossi *et al.*, 2006). Pol α -primase synthesizes an RNA primer at the 5' end of each Okazaki fragment. After initial primer synthesis, polymerase switching occurs, whereby pol α is removed and pol δ binds (Rossi *et al.*, 2006). Pol δ then adds nucleotides to the 5' end to extend the Okazaki fragment (Alberts, 2003). Upon the convergence of two fragments, the RNA primer is displaced and a single-stranded flap is formed (Aguilera and Gomez-Gonzalez, 2008; Rossi *et al.*, 2006). This flap is then cleaved by flap endonuclease 1 (FEN1) and RNase H, resulting in a nick, which is subsequently sealed by DNA ligase I (Aguilera and Gomez-Gonzalez, 2008; Rossi *et al.*, 2006).

Strand coordination

DNA is replicated in a manner that results in a leading strand synthesized continuously and a lagging strand synthesized discontinuously. In order for this to be a simultaneous process, it is thought that two different DNA polymerases are coupled, as confirmed in both phage and bacterial systems (Johnson and O'Donnell, 2005). These polymerases coordinate with other associated factors to complete this task in both prokaryotic (McHenry, 1988) and eukaryotic (Tsurimoto and Stillman, 1989) replication. This coupling, however, creates a topological problem, where both DNA polymerases generate helical DNA strands that must either travel a helical path or turn behind the complex. It is most likely that the coordination of the leading and lagging-strand synthesis involves a DNA looping mechanism (Ashton *et al.*, 2013). This mechanism, referred to as the trombone model, requires the lagging strand to fold back and form a loop through the complex, allowing parallel polymerization to proceed together in the 5' to 3' direction, thus preventing replication fork stalling. The trombone model has been observed and verified by EM (Alberts *et al.*, 1983). Figure 1(b) depicts the trombone model.

Replication Factories

Because DNA replication is highly coordinated, it is thought that the process is completed by replication complexes that have all the required components. It is still under debate when these complexes are formed. Evidence from biochemical data indicates that multiprotein replication complexes containing

Figure 1 (a) The coordinated activity of proteins and enzymes at the replication fork to process both leading and lagging strand daughter DNA strands. After the parental DNA is unwound by the primosome (DNA helicase and DNA primase), two DNA polymerases synthesize the leading and lagging strand. The lagging strand requires synthesis between separate Okazaki fragments. (b) DNA synthesis with coupled polymerases, resulting in lagging strand looping. Reprinted from Alberts, B., 2003. DNA replication and recombination. Nature 421, 431–435, with permission from Macmillan Publishers Ltd, © 2003.

all required elements form prior to initiation of DNA replication (Tom *et al.*, 1996), while images from live-cell microscopy suggest the interaction of each component within the complex to be highly dynamic (Sporbert *et al.*, 2002).

Replication factories appear to be fixed on a diffuse nucleoskeleton, and the newly synthesized DNA appears to move through replication factories. Images obtained with EM confirm this theory, as the DNA helicase remains intact throughout the replication process, rather than splitting between the two newly synthesized daughter DNA strands (Wessel *et al.*, 1992). Time-lapse fluorescence microscopy in live cells further validates the anchoring of replication factories in the nucleus, as the labeled foci do not appear to change position (Leonhardt *et al.*, 2000).

The genetic information of the eukaryotic and mammalian cell is contained within the chromatin structure of the nucleus. In order to fully replicate the encoded DNA, each cell must contain enough origins to fire once during the process, as re-firing can result in unbalanced genes and fragile replication forks. These origins are grouped into ‘replicons’ that simultaneously replicate large sections of the chromosome. Replicons further cluster together into foci at distinct regions of the nuclear matrix or nucleoskeleton. Each focus contains the proteins and enzymes necessary to replicate DNA, which are themselves organized as ‘replication factories.’ These complexes have been identified microscopically as electron-dense bodies in HeLa cells (Hozak *et al.*, 1993), with replication factories approximately 150 nm in diameter.

DNA Damage Response

During the S phase of every cell cycle, each cell must accurately duplicate DNA to ensure genomic integrity. At the same time, these cells are constantly bombarded by insults that threaten

to compromise the DNA template and, consequently, replication. DNA damage is a continuous phenomenon that is the by-product of these endogenous and exogenous processes and exposures. Exogenously, chemicals or radiation from ionizing (IR) or ultraviolet (UV) sources can damage DNA, while the endogenous damage results from oxidative stress induced by the reactive oxygen species (ROS) of cellular metabolites. Approximately 10^{-10} mistakes are generated per base pair in each DNA replication cycle (Polycove and Feinendegen, 2003). DNA damage leads to stalled replication forks, and failure to repair DNA lesions can result in mutations or large-scale genomic changes that may endanger cellular, and perhaps organism, viability. Consequently, cells have an array of methods to cope with DNA damage to avert fork stalling or facilitate fork restart when stalling occurs.

DNA damage response is a cascade of events involving sensors, transducers, and effectors (Marechal and Zou, 2013). Once a disruption in the DNA structure is identified, signal transduction pathways trigger a response, which often involve slowing down the cell cycle to allow for proper DNA repair. The most common responses involve activation of the ATM (ataxia telangiectasia mutated) and ATR (ATM and Rad3 regulated) protein kinases. Double-stranded breaks in DNA from IR and ROS damage often activate an ATM-related response, while DNA lesions and other types of DNA damage that create ssDNA trigger the ATR pathway. The viability of mammalian cells generally requires ATR, but not ATM. However, they are both important for genomic stability (Marechal and Zou, 2013; Smith *et al.*, 2010).

Damage Signaling

ATM-related damage response

When a double-stranded break on the DNA is sensed, the MRN complex (Mre11, Rad50, and Nbs1) binds and recruits

ATM to the damage site (Figure 2). ATM switches from an inactive homodimer to a particularly active monomer via autophosphorylation to initiate binding near the DNA damage site (Smith *et al.*, 2010). Once bound ATM is able to phosphorylate histone H2AX at Ser139, referred to as γ H2AX. MDC1 binds to γ H2AX and Nbs1 to indirectly associate with ATM, and possibly allow phosphorylation of additional H2AX proteins at nearby nucleosomes along the chromatin structure (Marechal and Zou, 2013).

Activated ATM can signal many other proteins involved in both DNA repair and other cellular checkpoint processes, including Chk2, p53, SMC1, BRCA1, NBS1, CtIP, MDC1, and p53BP1 (Smith *et al.*, 2010). For example, after ATM phosphorylates p53 at Ser15, the kinase inhibitor p21 inhibits cyclin E/A-Cdk2 leading to G1 to S phase stalling. The G2/M

checkpoint also involves p53 and transactivation of p21 (Bolderson *et al.*, 2009). Both p53 and p21 regulate cell cycle arrest, repair, and apoptosis.

ATR-related damage response

ATR is known to play an essential role in replication fork progression. Figure 3 illustrates an example of an ATR-related response. When DNA polymerases encounter damage, such as a lesion, they will often halt DNA synthesis. RPA will coat the long stretches of ssDNA that are created as the DNA helicase continues to unwind the parental strand. Nucleotide excision repair, mismatch repair (MMR), long-patch base excision repair (BER), postreplication repair, end resection at double-strand breaks, or telomere erosion can also expose ssDNA to RPA. The Rad17–RFC complex senses the ssDNA and dsDNA junction and loads the 9–1–1 complex (Rad9–Rad1–Hus1) to dsDNA. ATR-interacting protein (ATRIP) can bind to RPA, thereby recruiting ATR to damaged DNA. Mediator proteins such as TopBP1, Claspin, Timeless, and Tipin stimulate ATR activity. ATR phosphorylates Chk1, resulting in replication checkpoint and DNA damage responses. ATM can also activate other proteins such as BRCA1, MCM, p53, and parts of the RPA complex (Marechal and Zou, 2013; Smith *et al.*, 2010; Tibbetts *et al.*, 1999).

Effector proteins

Chk1 and Chk2

Effector proteins are important to the regulation of DNA replication and repair in the S phase. Chk1 and Chk2 are two such proteins that have been well-characterized. Chk1 is phosphorylated by ATR at Ser319 and Ser345, while Chk2 is phosphorylated by ATM at Thr68 within a Ser-Gln/Thr-Gln (SQ/TQ) rich domain. Phosphorylated Chk1 and Chk2 are

Figure 2 Example of an ATM-related response. (1) In the event of a double strand break (red X), the MRN complex (2) senses the damage and recruits ATM (3). Mediator proteins (4) aid the response for ATM to phosphorylate and activate the effector protein Chk2 (5).

Figure 3 Example of an ATR-related response. (1) In response to DNA damage (red X) from DNA helicase unwinding faster than DNA synthesis, RPA covers stretches of ssDNA. (2) The Rad17–RFC2–5 complex loads the RFC 911 complex (Rad9, Rad1, and Hus1) to dsDNA. (3) ATRIP recruits ATR. (4) With help of mediator proteins, such as TopBP1, Claspin, Timeless, and Tipin, (5) ATR phosphorylates effector proteins, such as Chk1.

thought to detach from DNA and influence proteins involved in cell cycle progression, apoptosis, and gene transcription. For example, they inactivate types of Cdc25 phosphatases that inhibit Cdk1/cyclin B and Cdk2-cyclin E kinases, leading to G₂ to M-phase and G₁ to S-phase arrest, respectively. The resulting cell cycle arrest allows time for DNA repair. Activated Chk1 regulates Wee1 kinase (cell cycle control) and histone H3 phosphorylation (regulation of gene transcription due to DNA damage), and plays a role in recombination through Rad51 and BRCA2 phosphorylation (Smith *et al.*, 2010). Activated Chk2 regulates p53, BRCA1, and transcription factors, including FOXM1 and E2F1.

p53

p53 is a key responder to DNA damage and a major safeguard against the introduction of inheritable mutations into the genome through the replication of damaged DNA (Harris and Levine, 2005). In the absence of DNA damage, p53 is inactivated by its negative regulator, Mdm2. Upon DNA damage or other stresses, various pathways, including ATM and ATR, are activated. Once activated, the ATM and ATR kinases activate their downstream kinases, including Chk1, Chk2, and the MAP kinase p38, which phosphorylate p53; causing it to dissociate from Mdm2. Activated p53 binds DNA and activates expression of several genes, including the AF1/CIP1 gene encoding for p21. p21 then forms a complex with and inhibits CDK2 activity. The ensuing cell cycle arrest gives cells time to repair the damaged DNA. When DNA damage is beyond repair, p53 promotes programmed cell death or apoptosis to prevent accumulation and proliferation of cells harboring potentially oncogenic mutations in their genomes.

The importance of p53 in monitoring DNA damage and regulating DNA repair in normal cells is highlighted by the prevalence of mutations in the gene (TP53) encoding the p53 protein in tumors. Mutations in TP53 are present in about 50% of all human malignancies (Muller and Vousden, 2013). An inherited TP53 mutation has been found to be responsible for the cancer predisposing Li-Fraumeni syndrome (Muller and Vousden, 2013). These individuals develop tumors in their early adulthood. Mutant p53 is unable to bind to DNA, making it an ineffective transcriptional regulator. Therefore, it cannot induce p21 protein expression to stop cell cycle progression in response to DNA damage. Consequently, DNA synthesis continues through the damaged sites, creating inheritable mutations in daughter cells. Accumulation of these mutations in the genome eventually leads to malignancy. Therefore, a functional p53 plays an essential role in maintaining genome integrity and suppressing tumorigenesis.

DNA Repair Mechanisms

Direct reversal

Some modifications to nucleotides can simply be reversed chemically without requiring a template or breaking the phosphodiester backbone of DNA. This type of repair is referred to as direct reversal. An example of this type of repair is the alkylation of guanine that creates an O⁶-methylguanine lesion. O⁶-alkylguanine DNA alkyltransferase (AGT, MGMT, or AGAT) removes the methyl group from O⁶-methylguanine by

transferring the methyl group to a cysteine residue present in MGMT. As a result the lesion reverts back to the correct guanine nucleotide.

BER

The BER pathway is a process that repairs the simplest types of lesions due to DNA damage. BER utilizes a number of specialized glycosylases that can recognize specific nucleotide modifications that require repair. Base modifications recognized by this pathway include nucleotide deaminations, alkylations, oxidations, and spontaneously formed apurinic (AP) sites. Typical deamination reactions that occur during the cell cycle result in the conversion of cytosine to uracil, adenine to hypoxanthine, guanine to xanthine, and 5-methylcytosine to thymine within the DNA structure. Alkylation most commonly results in the addition of methyl groups to the nitrogen residues found in nucleotides. The oxidation of nucleotides is the result of oxygen metabolism, producing superoxide and hydroxyl free radicals, and generating ROS that modify nucleotides. The most common oxidation product is 8-oxo-deoxyguanosine, which can base pair with adenosine and introduce a point mutation if not repaired prior to replication. AP sites result from the hydrolytic cleavage of the glycosidic bond that holds a base in place in the DNA strand. BER is essential for the repair of an estimated loss of ~5000 purines per cell per day.

To remove lesions, the BER pathway utilizes modification-specific glycosylases to scan DNA for errors. Once a lesion is found, the glycosylase 'flips' the base into its damage-specific binding pocket where the N-glycosidic bond is cleaved and the base is removed from the DNA strand, leaving an AP site in its place. A single-strand break is then introduced at the AP site by AP endonuclease, or by the glycosylase itself if it has AP lyase activity. The broken ends are processed by end-processing enzymes such as polynucleotide-kinase-phosphatase (PNKP). DNA repair synthesis then replaces the missing base. There are two modes of DNA repair synthesis: short patch and long patch. In short patch BER, just the single missing base is replaced. The DNA polymerase that performs this function is pol β . In long-patch BER, 2–10 nucleotides are replaced. The first missing base is still replaced by pol β , but then pol δ and pol ϵ in concert with PCNA replace an additional series of nucleotides. In this process, the 5' end of the broken strand is displaced by the new synthesis, and the resulting flap of displaced DNA is removed by FEN1. To complete BER, the remaining nick in the repaired strand is ligated by DNA ligase III and the cofactor XRCC1 in short-patch repair, and by DNA ligase I in long-patch repair (Figure 4).

Nuclear excision repair

The nuclear excision repair (NER) pathway finds and removes bulky modifications that may be present in DNA and interfere with replication (de Laat *et al.*, 1999; Dijk *et al.*, 2014; Le May *et al.*, 2010). These modifications include the addition of methylation groups, oxygen groups, heterocyclic amines found in cooked food, and benzo(a)pyrene-diolepoxide (BPDE) adducts. BPDE is a noted carcinogen derived from the metabolic processing of benzo(a)pyrene present in automobile exhaust, cigarette smoke, and burned meat. NER also removes adducts acquired during chemotherapy, such as those created

Figure 4 The base excision repair (BER) pathway.

by cisplatin. As such, upregulation of proteins involved in NER are often associated with acquired chemoresistance by patients treated with lesion inducing drugs (Li *et al.*, 1998; Li and Melton, 2012). Perhaps the most essential damage repaired by NER is the damage due to UV exposure. The two major UV photoproducts are cyclobutane pyrimidine dimers (CPD) and pyrimidine (6-4) pyrimidone photoproducts. A deficiency in any one of the XP proteins (XPA through XPG) required for NER results in the condition known as xeroderma pigmentosum (XP), which, like XP 'variant' (XPV) is characterized by extreme sensitivity to sunlight. Patients with XP must avoid sunlight and, when unprotected, have a 10 000-fold higher incidence of non-melanoma skin tumors and a 2000-fold higher incidence of melanoma before the age of 20 than people without the deficiency (Kraemer *et al.*, 1994).

As opposed to the numerous glycosylases employed in BER, NER relies on the XPC–RAD23B protein complex and the accessory DDB1/DDB2 heterodimer (XPE) to constantly scan the genome for specific distortions in the DNA. XPE is important for the identification of some types of distortions that XPC–RAD23B is unable to detect on its own (Dijk *et al.*, 2014). When the complex identifies a distortion, transcription factor II H (TFIIH), XPA, and XPG are recruited to the site. The XPB and XPD subunits of TFIIH act as a helicase to unwind 22–29 nucleotides surrounding the adduct. RPA binds and protects the resulting ssDNA. XPG makes an incision on the 3'

side of the DNA strand containing the modification, while the XPF–ERCC1 complex makes an incision on the 5' side. The damaged single strand is removed, and the 22–29 nucleotide gap is filled in by the PCNA replication complex. The remaining nick is ligated and NER is complete (Figure 5).

MMR

MMR is a repair pathway that addresses the DNA mismatches that occur during replication and other stages of the cell cycle (Hsieh and Yamane, 2008; Iyer *et al.*, 2006; Li, 2008). A common source of mismatches is the misincorporation of nucleotides during replication, which occurs only once in every 10^7 bp. In the event of an incorporation error, MMR repairs the misincorporations and, in doing so, increases the fidelity of replication by 50- to 1000-fold (Iyer *et al.*, 2006). In addition to the normal replicative misincorporation, there are other sources of mismatches repaired through the MMR pathway. These include rare tautomeric forms of nucleotides that can form noncanonical base pairs. For example, the rare imino form of cytosine can base pair with the common amino form of adenosine, and the rare enol form of guanine can mispair with the common keto form of thymine. Other anomalous base pairings can result with ionized nucleotides or with atypical nucleotide conformations (syn-anti and wobble pairing) (Echols and Goodman, 1990; Friedberg *et al.*, 1995). Often mismatches occur in regions of the genome with short 1–5 bp repeats. These mismatches are the result of replication slippage, also known as slipped-strand mispairing, where regions of repeats on the newly synthesized strand are duplicated, or repeats on the template strand are omitted, causing an insertion or deletion (Tautz and Schlotterer, 1994). Other mismatches can result from damage to a nucleotide, including alkylation of nucleotides, adduct formation from carcinogens or chemotherapeutic agents (such as cisplatin) (Hang, 2004; Wozniak and Blasiak, 2002), and the creation of UV photoproducts (Reichrath and Rass, 2014). Finally, genetic recombination can result in mismatches in heteroduplex strands, which are due to sequence differences present in the two strands (Lichten *et al.*, 1990; Reenan and Kolodner, 1992).

The process of MMR in *E. Coli* has been fairly well defined (Figure 6; Iyer *et al.*, 2006; Joseph *et al.*, 2006). The polypeptide MutS initiates MMR by recognizing and binding as a dimer to mismatch regions. This binding signals the recruitment of additional dimeric protein, MutL. The MutS–MutL complex activates several downstream repair processes, including the activation of the latent endonuclease, MutH. Activated MutH incises the unmethylated strand of newly synthesized DNA at hemi-methylated GATC sites. The single-strand break serves to distinguish the mismatch strand from the template, allowing excision repair to begin on the broken strand. The site of the nick on the new strand is not significant, as it can be either 5' or 3' to the site of the mismatch, and does not have to be made by MutH or be within a GATC sequence.

The MutS–MutL complex can also activate DNA helicase II and several single-strand-specific exonucleases. DNA helicase II unwinds the DNA starting at the site of the single-strand break. Unwinding occurs preferentially toward the site of the mismatch, whether the single-strand break is upstream or downstream of the mismatch, suggesting that the MutS–MutL complex plays a role in coordinating the helicase. As the

Figure 5 The nuclear excision repair (NER) pathway.

broken strand is unwound, it is digested by several exonucleases. When unwinding occurs 5' of the mismatch, ExoVII and RecJ utilize their 5' → 3' exonuclease activity to hydrolyze the strand. When unwinding starts 3' of the mismatch, the strand is hydrolyzed by the 3' → 5' exonuclease activity of ExoI, ExoVII, or ExoX. After removal of the mismatch, DNA polymerase III holoenzyme synthesizes the missing segment, and DNA ligase seals the remaining nick.

MMR in eukaryotes is not as well characterized as in bacteria (Modrich, 2006). Several homologues for MutS have been found in eukaryotes, and have been designated MSH1–MSH6. These proteins are active as heterodimers. In humans, MSH2 pairs with MSH6 (MutS α) or with MSH3 (MutS β). Homologues for MutL have also been identified. They have been named MLH1, MLH2, MLH3, PMS1, and PMS2. These MutL homologues also form heterodimers. In humans, the MLH1–PMS2 heterodimer (MutL α) is capable of supporting repair initiated by MutS α or MutS β . A MLH1–PMS1 heterodimer (MutL β) has also been identified, but its function is unknown. No homologue for MutH has been identified in eukaryotes, and it is not known how excision repair is targeted to the strand containing the mismatch. It has not been shown that helicase activity is involved in eukaryotic MMR. Additionally, only one exonuclease (ExoI) has thus far been shown to be involved in the eukaryote system. PCNA and at least DNA polymerase δ are involved in the DNA synthesis required to replace the excised sequence.

Translesion DNA synthesis

Translesion DNA synthesis (TLS) represents an important survival mechanism for cells. It is a DNA damage tolerant process rather than a DNA repair process, as it enables the replication fork to bypass the encountered damage. It acts as a

quick fix for the damage by minimizing the length of time that replication fork stalling can threaten cell viability, while creating a double-strand product and a sister chromatid. This product can be used as a substrate or template for subsequent repair by mechanisms such as NER, BER, and homologous recombination (Prakash *et al.*, 2005; Saugar *et al.*, 2014; Waters *et al.*, 2009).

During conventional replication, DNA priming and elongation are conducted by highly accurate replication polymerases (Pol α , Pol δ , Pol ϵ , and Pol γ) that are present in the PCNA-based replication complex. The specificities of these polymerases is due in large part to the concise fit with which the polymerase encloses the template DNA. This exacting fit ensures that the active site of the polymerase reliably inserts the correct nucleotide into the newly synthesized DNA strand. However, in the event a DNA lesion is encountered, the polymerase is unable to accommodate such a bulky modification, which results in stalling at the replication fork. In order to accommodate these lesions, special TLS polymerases (Table 1) are required.

In order to switch between replicative polymerases and TLS polymerases, ubiquitinated PCNA (at lysine 164 by the Rad6–Rad18 protein duplex) is essential (Yang *et al.*, 2013). The TLS polymerases, as listed in Table 1, have a less restrictive conformation with DNA, allowing them to handle the unusual size of the lesion and still insert nucleotides (Prakash *et al.*, 2005; Yang, 2014). Even though the replication complex can continue synthesis beyond the lesion, a mutation has now been introduced into the DNA. The degree of error involved is dependent upon both the type of lesion and the TLS polymerase used in the bypass (Prakash *et al.*, 2005).

Often, more than one TLS polymerase is required to move past a lesion. For instance, in bypassing some thymidine

Figure 6 Mismatch repair (MMR) in *E. Coli*. Newly synthesized DNA containing a mismatch is recognized by MutS dimer. MutS recruits MutL to the site of mismatch. The MutS–MutL complex recruits and activates latent MutH. MutH incises the newly synthesized strands at hemi-methylated (5')-GATC-(3') sites in duplex DNA. The incision used in repair can be either 5' or 3' to the site of the mismatch. Helicase II begins unwinding DNA from the site of incision toward the site of mismatch. Single-strand-specific exonucleases digest the unwound strand containing the mismatch. If the incised strand is unwound in the 5' to 3' direction, ExoVII or RecJ are the exonucleases that digest the broken strand. If the incised strand is unwound in the 3' to 5' direction, ExoI, ExoVII, or ExoX are the exonucleases involved in digestion. DNA polymerase III holoenzyme resynthesizes the removed segment of DNA and DNA ligase seals the remaining nick (not shown).

Table 1 Identified polymerases involved in translesion synthesis (TLS)

Family	Gene	Protein
A	POLQ	Pol θ
B	REV3 and REV7	Pol ζ
Y	REV1	Rev1
Y	POLH	Pol η
Y	POLI	Pol ι
Y	POLK	Pol κ
A	POLN	Pol ν

dimers, such as 6-4 photoproducts, the TLS polymerase pol η will accurately position an adenosine base opposite the first thymidine base with the correct Watson–Crick base pairing but will insert the next adenosine in a *syn* orientation that results in Hoogsteen pairing with the second thymidine. In this situation, pol η will subsequently be replaced by a more error-prone polymerase, such as pol γ , to extend the DNA past the lesion, where the more accurate replicative polymerase can then continue normal synthesis (Chou, 2011). When bypass results in the wrong base being inserted in the newly

synthesized strand, subsequent DNA repair of the original lesion may use the incorrect sequence as a template for repair, which results in a point mutation within the genome. Multiple point mutations have been shown to drive normal cells to become cancerous, or cancer cells to acquire chemoresistance (Figure 7).

The importance of TLS is best illustrated in XPV patients. These patients lack one of the TLS polymerases (i.e., Pol η), which enables bypass of CPD typically caused by UV exposure. Even though XPV patients have an intact NER pathway, they suffer from the same condition as patients without NER – that is, they have acute sensitivity to UV exposure, which results in a dramatic increase in mutations and incidence of skin cancer (Kraemer *et al.*, 1994; Menck and Munford, 2014).

Double-strand break repair

The most serious, but less common, form of DNA damage is a double-stranded break. Not repairing these damages leads to apoptotic cell death. In a model involving both the ATM and ATR pathway, the ATM pathway first responds to dsDNA breaks. DNA-end resection, involving ATM, MRN complex, CtIP, and BRCA1, occurs when specialized nucleases create

Figure 7 The TLS lesion repair mechanism.

ssDNA. RPA also binds to the newly created ssDNA (Huertas, 2010) activating the ATR–Chk1 pathway.

Double-strand break repair mechanisms

Mechanisms for repairing double-strand breaks mainly involve (1) NHEJ (nonhomologous end-joining) and (2) HR (homologous recombination repair) (Huertas, 2010). NHEJ occurs during any phase of the cell cycle, and was thought to be error-prone because it involves rejoining broken dsDNA regardless of the sequence, but emerging evidence shows otherwise (Betermier *et al.*, 2014). HR, on the other hand, requires a homologous template and occurs during the S and G₂ phase of the cell cycle (Smith *et al.*, 2010).

NHEJ repairs most double-strand breaks caused by ionizing radiation. In the canonical model for NHEJ, the Ku70/80 heterodimer recruits DNA-dependent protein kinase to the two ends of dsDNA in a ring-like structure. This allows the XRCC4-ligase IV complex to ligate the ends of DNA with the aid of the XRCC4-like factor (Betermier *et al.*, 2014; Bolderson *et al.*, 2009). Alternative models of NHEJ have also been described (Betermier *et al.*, 2014).

In a common model of HR, the ends of the ssDNA, such as from sister chromatids, are used as templates for repair. In vertebrates, Cdk appears to phosphorylate CtIP, which controls DNA strand resectioning via cell cycle regulation. Yeast studies reveal that HR occurs mainly in the S and G₂ phase of the cell cycle, and HR in vertebrates is thought to be regulated similarly. DNA strand resection by the Mre11 endonuclease of the MRN complex helps create tracks of ssDNA/RPA, with the aid of BRCA1 and CtIP. More single strands are formed with other nucleases and helicases, such as

Exo1 and BLM, where RPA binds. These events can activate the ATR pathway. After strand resectioning, BRCA2 loads Rad51 recombinase onto the ssDNA, which displaces RPA and starts DNA damage repair using the sister chromatid as a template. BRCA1 responds to DNA damage through its role in DNA repair, checkpoint activation, and gene transcription (Smith *et al.*, 2010).

Conclusions

- The synthesis (S) phase of the cell cycle is of critical importance to precisely replicating the genomic information encoded in the nucleus of the cell.
- The G1 to S phase transition requires the activation and signaling of a number of specific components, including CDKs and Myc.
- The actual process of DNA replication in mammalian cells is complex, requiring the coordinated activity of specific proteins and enzymes. The exact mechanism involved in the simultaneous, dual processing of the DNA strands, however, is currently unknown.
- DNA damage is a constant threat to the genomic integrity of the cell. As a result, the cells have a number of mechanisms to respond to the damage incurred. This will allow the cell cycle to continue.

Introduction

The chromosomal passenger complex (CPC) consisting of Aurora B, Borealin, INCENP, and Survivin is essential for mitosis and meiosis (Carmena *et al.*, 2012). Activation of Aurora B occurs upon its interaction with the C-terminus of INCENP while the other passenger proteins ensure that Aurora B is properly localized. The CPC shows a dynamic pattern of localization allowing it to regulate multiple mitotic events. During prometaphase and metaphase, the CPC concentrates at the inner centromere where it is essential for error correction, a process that destabilizes inappropriate kinetochore–spindle attachments (Carmena *et al.*, 2012). Aurora B is also essential for phosphorylation of histone H3 at serine 10 which releases HP1 proteins from heterochromatin during mitosis to allow chromosome compaction. Aurora B also contributes to release of cohesin from chromosome arms during prophase, a process that helps to maintain genomic stability. At anaphase the CPC relocates to the spindle midzone where it coordinates cleavage furrow formation. At cytokinesis, CPC at the midbody inhibits abscission in response to chromosome bridges. Evidence exists for functional conservation of the CPC in diverse organisms including fungi and amoebozoans (Chen *et al.*, 2007). A potential homologue of INCENP has also been identified in plants (Kirioukhova *et al.*, 2011). The CPC appears to be a relatively early addition to the eukaryotic lineage and an essential component of animal cell division.

Identification of the Core CPC Members

Discovery of CPC started with INCENP. By raising antibodies against the bulk proteins of the chicken mitotic chromosome scaffold, an antibody recognizing two proteins concentrated at the pericentromere was identified. The proteins were termed inner centromere proteins (INCENPs) and subsequently found to arise from alternative splicing of the incenp mRNA (Cooke *et al.*, 1987). INCENPs displayed dynamic localization during mitosis, localizing to inner centromeres before chromosome segregation and to the spindle midzone and midbody during cytokinesis and telophase, respectively. This pattern of localization led to the ‘chromosomal passenger’ hypothesis which stated that various mitotic events, such as chromosome segregation and cytokinesis, were regulated by proteins that localize to chromosomes during early mitosis and transfer to the spindle midzone during late mitosis (Cooke *et al.*, 1987). Further functional analysis revealed that INCENP played a role in chromosome congression and segregation (Ainsztein *et al.*, 1998). Aurora B was the next CPC family member identified, but not in that capacity. Aurora B was identified as the budding yeast mutant *Ipl1* which underwent whole genome polyploidization at the restrictive temperature (Chan and Botstein, 1993). Studies from another direction identified

Survivin as an antiapoptotic protein overexpressed in cancer. Localization patterns of Aurora B, Survivin, and INCENP were similar and it was not long before all three were found to be in a complex providing a direct link between chromosomal passenger proteins and mitotic checkpoint control (Kim *et al.*, 1999). Shortly thereafter, a proteomic screen for novel human proteins associated with histone-depleted mitotic chromosomes led to the discovery of Borealin, providing a glimpse of the core members of the CPC (Gassmann *et al.*, 2004).

Putting the CPC Together

INCENP, Survivin, and Borealin can be thought of as both a delivery and activation system for Aurora B. Binding of Aurora B to INCENP activates the kinase. Localization of this activity is just as important for CPC function, a role played by all CPC members. Ultimately, it is the catalytic activity of Aurora B that is responsible for the effects of the CPC. Aurora B is a member of the Aurora family of kinases that are related to the cAMP (cyclic adenosine monophosphate)-dependent, cGMP (cyclic guanosine monophosphate)-dependent, protein kinase C family of serine/threonine kinases (Carmena *et al.*, 2012). The family of Aurora kinases comprised of Aurora A, Aurora B, and Aurora C share the consensus motif $([R/K] \times [S/T]\Phi)$ but differ in substrates mainly by specific distribution patterns within the cell. For instance, Aurora A localizes to the mitotic spindle, centrosomes, and midbody while Aurora B localizes to chromosome arms, inner centromeres, the central spindle, and midbody. Localization of Aurora C is similar to Aurora B; however, Aurora C is mainly expressed in germ cells and the morula during embryonic development. Interestingly, the differential function of Aurora A and Aurora B is achieved by a single amino acid difference (Eyers *et al.*, 2005). Basal activation of Aurora B is initially mediated by binding the conserved C-terminal IN-box of INCENP. Aurora B then phosphorylates INCENP at conserved threonine-serine-serine (TSS) motif on INCENP and threonine 232 in the activation loop of Aurora B resulting in full activation of Aurora B (Bishop and Schumacher, 2002). Microtubules can also activate Aurora B and microtubule-mediated activation of Aurora B is stimulated by telophase disk protein 60 (TD-60) (Rosasco-Nitcher *et al.*, 2008).

To understand the critical role of CPC subunits in localizing Aurora B activity, a view of how the subunits are assembled is essential (Figure 1). The C-terminus of Survivin and the N-terminus of Borealin bind the N-terminus of INCENP in a three-helix bundle to facilitate complex formation and mediate targeting of the CPC to various intracellular localizations (Jeyaprakash *et al.*, 2007). While the N-terminus of INCENP binds Borealin and Survivin, the C-terminus binds Aurora B. The N- and C-terminus of INCENP are separated by a large, unstructured region which contains

Figure 1 Subunits of the CPC. The CPC is composed of INCENP, Aurora B, Survivin, and Borealin. Complex formation is facilitated by a three-helix bundle between INCENP, Survivin, and Borealin. The central region of INCENP contains an HP-1 binding site and a coiled-coil domain which can interact with microtubules. The C-terminus of INCENP contains a highly conserved IN-box motif that mediates the interaction with Aurora B. The C-terminus of INCENP also contains a conserved TSS motif which is phosphorylated by Aurora B and consequently stimulates Aurora B activity. The N-terminus of Survivin contains a conserved Zn^{2+} -binding BIR domain. The central region of Borealin contains multiple CDK1-mediated phosphorylation sites and the C-terminus of Borealin contains a conserved dimerization domain.

the heterochromatin binding protein-1 (HP-1) binding motif and multiple CDK1 phosphorylation sites (Carmena *et al.*, 2012). Survivin is a well-studied, multifunctional protein that contains an N-terminal baculoviral inhibitor of apoptosis (BIR) domain bound to Zn^{2+} . The C-terminal α -helix of Survivin interacts with INCENP and Borealin (Jeyaprakash *et al.*, 2007). Survivin was originally described as an inhibitor of apoptosis protein (IAP) that was proposed to negatively regulate cell death in mitosis (reviewed in Altieri, 2010). Numerous studies have connected high levels of Survivin with a reduction of apoptosis. Also, Survivin is overexpressed in many types of human cancer. However, knockdown or knockout of Survivin does not initially sensitize to apoptosis, but does ultimately result in apoptosis secondary to failed cytokinesis and accumulation of DNA damage (Yang *et al.*, 2004). Therefore, Survivin, at endogenous levels does not suppress apoptosis. Overexpressed Survivin, either in an experiment setting, or as a result of upregulation in cancer antagonizes pro-apoptotic signals. Survivin forms a dimer *in vitro*; however, the dimerization interface is disrupted when Survivin binds Borealin, thus inhibiting homodimer formation when in complex with the CPC (Jeyaprakash *et al.*, 2007; Verdecia *et al.*, 2000; Chantalat *et al.*, 2000). Survivin is phosphorylated by multiple kinases including Aurora B, CDK1, Plk1, and Casein kinase-2 providing multiple levels of regulation (Nogueira-Ferreira *et al.*, 2013).

Borealin interacts with Survivin and INCENP via two N-terminal α -helices located between amino acids 15 and 76 (Jeyaprakash *et al.*, 2007). Interestingly, the yeast homolog of Borealin, Nbl1, is roughly half the size of the vertebrate Borealin proteins; however, all Borealin homologs contain the N-terminal helix that mediates triple-helix bundle formation with INCENP and Survivin (Carmena *et al.*, 2012). The central region of Borealin (amino acids 106–219) contains multiple

CDK1 phosphorylation sites which have been linked to centromere localization of the CPC (Kaur *et al.*, 2010; Tsukahara *et al.*, 2010). The central region of Borealin also interacts with the ESCRT-III subunit Shrb/CHMP4C to regulate cytokinesis (Capalbo *et al.*, 2012; Carlton *et al.*, 2012). Deletion of part of the central region of Borealin created a protein that was more dramatically upregulated in response to proteasome inhibition, suggesting that this region may contribute to Borealin metabolism (Date *et al.*, 2012). Like Survivin, Borealin is overexpressed in a diverse group of human cancers, possible due to its regulation by the E2F family of cell cycle regulated transcription factors (Date *et al.*, 2007). The C-terminus of Borealin (amino acids 224–280) contains a dimerization domain whose structure has been solved (Bourhis *et al.*, 2009). Threonine 230 within the dimerization domain is phosphorylated by the mitotic kinase Mps1 (Bourhis *et al.*, 2009; Jelluma *et al.*, 2008). Mutation of T230 to either alanine or valine impairs Aurora B activity and chromosome alignment *in vivo*. However, the T230A mutant disrupts dimer formation while the T230V stabilizes it (Bourhis *et al.*, 2009). Therefore, the role of dimerization in Borealin function is unresolved. Borealin is also sumoylated in a RanBP2-dependent manner during early mitosis and the isopeptidase SENP3 catalyzes removal of SUMO2/SUMO3 from Borealin (Klein *et al.*, 2009). However, the function of sumoylation is unclear given that mutation of all lysines on Borealin does not result in obvious mitotic defects.

CPC during the Approach to Mitosis

During interphase, the CPC localizes to pericentromeric heterochromatin via INCENP binding to HP-1 (Ainsztein *et al.*, 1998). HP1 is recruited to heterochromatin by binding to histone H3 that is di- or tri-methylated at lysine 9 (H3K9me2/H3K9me3). Phosphorylation of serine 10 on H3, an event that begins in G2, displaces HP1 possibly to facilitate concentration of INCENP at centromeres during prometaphase (Carmena *et al.*, 2012). In an early study on isolated mitotic chromosomes phosphorylation of serine 10 of histone H3 was found as one of the most abundant modifications (Paulson and Taylor, 1982). Subsequent studies identified Aurora B as the major kinase responsible, and PP1 as the phosphatase counteracting this modification (Hsu *et al.*, 2000). During interphase, a number of kinases including Msk1 and Msk2 phosphorylate H3 at serine 10 to modulate transcription (Duncan *et al.*, 2006). Nonetheless, G2 phosphorylation of H3 at serine 10 by Aurora B marks the beginning of CPC activity in preparation for mitosis and provides one example of how the CPC controls its own localization.

Release of HP1 by serine 10 phosphorylation may also impact the pericentromeric heterochromatin environment. Centromeres are enriched in specific modified histones including H3K4me2, H3K36me2, and H3K9me2/H3K9me3. H3K9me2/H3K9me3 marks a large heterochromatin domain that extends beyond CenPA nucleosomes (Wang and Higgins, 2012). Evidence in fission yeast suggests that release of HP1 may be required to allow transcription of centromeric repeats to maintain a specific balance of histone modifications required for centromere function (Chen *et al.*, 2008). A similar

type of regulation may occur in mammals. For example, targeting the LSD1 H3K4-specific methyltransferase to a neocentromere resulted in the gradual loss of CenPA nucleosomes, reduction in centromere-associated noncoding transcripts, and loss of kinetochore markers (Bergmann *et al.*, 2011). Thus, the heterochromatin environment is essential for proper function of the centromere and phosphorylation of H3 at serine 10 likely contributes to this regulation. H3 phosphorylated at serine 10 plays a second key role in mitotic chromatin condensation. S10-phosphorylated H3 recruits Hst2 which deacetylates H4K16 allowing tighter nucleosome packing required for mitotic chromosome condensation (Wilkins *et al.*, 2014). Related to this finding is the observation that Aurora B is required for axial shortening of chromosomes which continues into until anaphase in mammalian cells (Mora-Bermudez *et al.*, 2007). Therefore, one of the most abundant Aurora B targets, serine-10 phosphorylated H3, plays multiple important roles in mitosis.

CPC in Mitosis

From prophase to telophase, localization of the CPC is dynamic and is an indication of the multiple roles the CPC plays in regulating mitotic progression and cell division. During early mitosis, the CPC is found at centromeres and diffusely localized along chromosome arms. Another key mitotic role of Aurora B is carried out during prophase. Along with Cdk1, Aurora B contributes to sister chromatid resolution by phosphorylating the cohesion-stabilizing protein Sororin (Losada, 2014; Dreier *et al.*, 2011). Phosphorylated Sororin dissociates from the cohesion subunit Pds5, which ultimately results in Wapl-mediated release of cohesion from chromosome arms. Polo-like kinase is also essential for prophase removal of cohesin, and works by phosphorylating cohesin subunits (Losada, 2014). Cells in which the prophase removal pathway is inhibited show an increase in chromosome loss upon completion of mitosis, indicating the importance of this pathway in maintaining genomic stability (Haarhuis *et al.*, 2013). As mitosis progresses, the CPC concentrates at inner centromeres where it participates in an essential, evolutionarily conserved surveillance mechanism required for high-fidelity chromosome segregation. The spindle assembly checkpoint (also known as the mitotic checkpoint) blocks entry into anaphase until all chromosomes attain a bipolar attachment to the spindle. The best recognized role of the CPC in this process is in 'error correction' where inappropriate spindle-kinetochore attachments are converted to unattached kinetochores that trigger the SAC.

The Spindle Assembly Checkpoint

Observations of mitotic animal cells indicated that initiation of chromosome segregation correlated with alignment of chromosomes at the metaphase plate. Furthermore, inhibiting spindle assembly with small molecules that disrupt the dynamic instability of microtubules ultimately halted cell cycle progression at mitosis. These observations suggested that a checkpoint coupled mitotic exit to chromosomal alignment

and spindle assembly (Rieder, 2011). Two seminal papers describing yeast mutants that fail to arrest in mitosis when exposed to microtubule-disrupting agents, termed mitotic-arrest deficient (*mad*) and budding-uninhibited by benzimidazole (*bub*), led to the idea that mitosis is indeed under checkpoint control (Li and Murray, 1991; Hoyt *et al.*, 1991). Additional research established that the fidelity of centromeres and kinetochores, the multi-protein complexes that connect chromosomes to the spindle, was essential for proper chromosome segregation (e.g., Spencer and Hieter, 1992). An elegant study that realized the importance of kinetochores in regulating the spindle assembly checkpoint showed that laser ablation of the last unattached kinetochore rapidly induced mitotic exit indicating that unattached kinetochores are the primary signal that activates the spindle assembly checkpoint (Rieder *et al.*, 1994). Not surprisingly, subsequent biochemical and cytological evaluation of *Mad* and *Bub* gene products indicated that many *Mad* and *Bub* proteins associate with kinetochores (Cheeseman, 2014). In particular, the homologous *mad2* gene product in *Xenopus laevis*, XMAD2, was described as a dynamic kinetochore-associated protein that bound to unattached kinetochores, where XMAD2 localization to kinetochores was reduced upon chromosome alignment, suggesting that *Mad2* was at the apex of spindle assembly checkpoint activation (Chen *et al.*, 1996). Additional genetic and biochemical studies indicated that *Mad2* interacted with an E3 ubiquitin ligase known as the anaphase promoting complex/cyclosome (APC/C) (Murray, 1992). The APC/C targets Cyclin B for proteasomal degradation to extinguish Cdk1 activity and drive mitotic exit. *Mad2* inhibits the APC/C to keep cells in a mitotic state until all chromosomes attain bipolarity (He *et al.*, 1997; Li *et al.*, 1997). Further characterization of homologous *mad* and *bub* genes in higher eukaryotes eventually led to the general conclusion that unattached kinetochores catalyze the formation of an inhibitory complex known as the mitotic checkpoint complex (MCC), composed of *Mad2*, Bub-related 1 (*BubR1*), *Bub3*, and the APC/C co-activator *Cdc20* (Figure 2). The MCC inhibits the APC/C by sequestering *Cdc20*, which leads to Cyclin B stabilization and spindle assembly checkpoint activation via sustained CDK1 activity (Figure 2). Formation of the MCC ceases only when sister kinetochores bind to microtubules from opposing spindle poles, which allows *Cdc20* to activate the APC/C. Consequently, activation of the APC/C leads to Cyclin B degradation, which inactivates CDK1 and induces mitotic exit.

Spindle Assembly Checkpoint and Inter-Kinetochore Tension

Because the spindle assembly checkpoint appeared to ensure proper attachment of kinetochores to spindle microtubules, it was not clear how improper kinetochore-microtubule attachments were sensed and regulated. For instance, when a single sister kinetochore is bound to the both spindle poles (merotelic) or both sister kinetochores are bound to microtubules from the same spindle pole (syntelic), initiating mitotic exit when merotelic or syntelic attachments persists often leads to chromosome mis-segregation resulting in the

Figure 2 The spindle assembly checkpoint. (a) Prior to anaphase initiation, unattached kinetochores generate an inhibitory complex composed of Mad2, BubR1, Bub3, and Cdc20, known as the MCC. The MCC effectively sequesters Cdc20, which is a co-activator of the E3 ubiquitin ligase APC/C. (b) When chromosomes become bi-oriented and kinetochores are stably attached to spindle microtubules, the MCC disassembles and Cdc20 is free to activate the APC/C. Active APC/C targets essential mitotic substrates such as Cyclin B and securin for proteasomal degradation ultimately leading to anaphase initiation and mitotic exit.

generation of daughter cells with unequal DNA content, known as aneuploidy (Kops *et al.*, 2005). Initially it was hypothesized that the physical tension that arises from bi-orientation of chromosomes, or sister-kinetochore attachment to opposite spindle poles, regulated the spindle assembly checkpoint given that bi-orientation is consistent with anaphase initiation and successful cell division (Rieder *et al.*, 1994). Indeed, application of tension on improperly attached chromosomes leads to anaphase initiation earlier compared to the absence of tension (Li and Nicklas, 1995). Additionally, it was observed that increased tension between sister kinetochores and anaphase initiation correlated with dephosphorylation of kinetochore proteins indicating that kinetochore chemistry is sensitive to tension and may link mitotic forces to checkpoint activation (Nicklas *et al.*, 1995). Further characterization of Mad and Bub proteins indicated that their kinetochore localization was regulated differentially in response to either kinetochore-microtubule attachment or sister-kinetochore tension (Waters *et al.*, 1998). Together, these observations led to speculation that either microtubule occupancy or physical tension induced by microtubule capture negatively regulated spindle assembly checkpoint activation. Yet again, observations of cell cycle dynamics in yeast mutants led to a molecular link between tension and spindle assembly checkpoint activation. The observation that yeast *cdc6* mutants, which are allowed to progress into mitosis without replicating their genome, activate the spindle assembly checkpoint despite attaching all kinetochores to microtubules was evidence that lack of tension between sister kinetochores was the primary activator of the spindle assembly checkpoint (Stern and Murray, 2001). Furthermore, the discovery that mutating the gene *Ipl1*, which had been described as a regulator of microtubule turnover at kinetochores, overcame the

tensionless arrest in *cdc6* mutants suggested that tension was sensed by the *Ipl1* gene product (Biggins and Murray, 2001). Altogether, these observations led to a more refined model of spindle assembly checkpoint regulation where unattached kinetochores initially activate the spindle assembly checkpoint and the checkpoint signal is inactivated when microtubules bind kinetochores (Figure 3). However, kinetochore-microtubule interactions that do not result in the physical separation of sister kinetochores are destabilized resulting in MCC formation and spindle assembly checkpoint activation (Figure 3). Only when kinetochores capture microtubules from opposing spindle poles is inter-kinetochore tension high enough to separate sister kinetochores and silence MCC production (Figure 3). Thus, activation of the spindle assembly checkpoint is sensitive to kinetochore-microtubule attachment, but also inter-kinetochore tension. The tension-regulated error-correction mechanism was ultimately identified as the CPC.

CPC and Error Correction

An attractive model that explains the role of the CPC in error correction is known as the spatial gradient model and suggests that Aurora B phosphorylates microtubule-binding kinetochore proteins under low inter-kinetochore tension which leads to dissociation of kinetochore-microtubule interactions (Figure 4; Carmena *et al.*, 2012). As chromosomes become bi-oriented and sister kinetochores are under high tension, Aurora B is spatially separated from the kinetochore and can no longer destabilize kinetochore-microtubule interactions. Indeed, sister chromosomes that have not bi-oriented display relatively unstable kinetochore-microtubule interactions,

Figure 3 Inter-kinetochore tension and error correction (a) Kinetochore–microtubule interactions that do not result in high tension between sister kinetochores (inter-kinetochore tension), such as merotelic or syntelic attachments, are erroneous and selectively destabilized, which enables MCC production and activation of the mitotic checkpoint. (b) When sister kinetochores attach to microtubules from opposing spindle poles, or bi-orientation, inter-kinetochore tension is high and kinetochore–microtubule interactions are stabilized ultimately silencing MCC production which promotes mitotic exit.

compared to bi-oriented chromosomes, which requires Aurora B kinase activity (Carmena *et al.*, 2012). Additionally, the core microtubule-binding kinetochore proteins of the KMN network, which consists of the Knl1 complex, the Mis12 complex, and the Ndc80/Hec1 complex, have been identified as Aurora B substrates and Aurora B-mediated phosphorylation reduces their affinity for microtubules *in vitro* (Welburn *et al.*, 2010). Moreover, an Aurora B FRET-sensor detects a gradient of Aurora B activity that is highest near inner centromeres (Figure 4; Fuller *et al.*, 2008). Thus, according to this spatial gradient model of CPC-mediated checkpoint activation, inner centromere localization of the CPC is paramount for regulating error correction and spindle assembly checkpoint activation. Localization of the CPC to inner centromeres during mitosis is common to yeast, zebra fish, frog, chicken, mouse, and human cells, suggesting that centromere accumulation is essential for the function of the CPC.

Recent studies in yeast suggest that the role of CPC in error correction may be more complicated than spatial restriction due to an inner centromere location. For example, yeast cells expressing the INCENP mutant (Sli15ΔN) are viable and exhibit normal chromosome segregation despite the fact that this mutant fails to bind Survivin and is unable to localize Aurora B to centromeres (Campbell and Desai, 2013). Therefore, yeast and animal cells may differ in the dependency on CPC centromere location for proper function. Some studies have detected CPC family members at the kinetochore, a finding that may be at odds with the spatial gradient model (Petsalaki *et al.*, 2011). However, PP1-dependent dephosphorylation of kinetochore substrates may help to counteract CPC that spreads from the inner centromere, especially when kinetochores are not under tension.

The Two-Histone Model of CPC Localization to Centromeres

Localization of the CPC to centromeres reportedly intersects with two histone modifications that overlap at inner centromeres: phosphorylated histone H3 at threonine 3 (pH3T3) and phosphorylated histone 2A at threonine 120 (pH2AT120) (Figure 5; Yamagishi *et al.*, 2010). Haspin kinase generates pH3T3, which is in turn bound by Survivin. The BIR domain of Survivin directly interacts with pH3T3 to recruit the CPC and this interaction can be regulated by pH, suggesting that the *in vivo* interaction could be regulated by the local environment (Jeyaparakash *et al.*, 2011). The CPC engages in positive feedback to maintain pH3T3 levels during mitosis. For instance, Aurora B directly phosphorylates Haspin at multiple residues during mitosis and mutation of these residues reduces pH3T3 (Wang *et al.*, 2011). Consistent with this observation, inhibiting Aurora B during mitosis leads to a reduction in pH3T3 levels. However, the mechanism of Aurora B-mediated regulation of Haspin activity is unknown because mutation of Aurora B phosphorylation sites does not reduce intrinsic kinase activity of Haspin. Aurora B phosphorylation might regulate the release of a Haspin inhibitor or facilitate substrate binding (Wang *et al.*, 2011). Dephosphorylation of pH3T3 is mediated by the phosphatase PP1γ–Repo-Man complex and Aurora B-mediated phosphorylation negatively regulates PP1γ–Repo-Man activity toward pH3T3 (Qian *et al.*, 2011). Thus, Aurora B positively regulates pH3T3 abundance by promoting Haspin kinase activity toward H3 and negatively regulating removal of pH3T3 by phosphorylating PP1γ–Repo-Man.

The second histone mark that dictates CPC localization to centromeres is generated by the kinetochore-localized kinase Bub1. Kinetochore-bound Bub1 generates pH2AT120 at the kinetochore, which recruits the Shugoshin proteins (Sgo1/Sgo2) (Yamagishi *et al.*, 2010). Sgo1/Sgo2 can bind CDK1-phosphorylated Survivin in yeast and Borealin in humans, which may explain why centromere accumulation of the CPC begins in late prophase when CDK1 activity is highest in the disassembled nucleus (Tsukahara *et al.*, 2010). Interestingly, the BIR domain of Survivin can bind the N-terminus of human Sgo1 *in vitro*, suggesting cross talk between the two-histone pathways (Jeyaparakash *et al.*, 2011). The CPC also indirectly engages in feedback with Bub1 to generate pH2AT120. For example, Aurora B kinase activity is essential for kinetochore targeting and activation of the mitotic kinase Monopolar Spindle 1 (Mps1) (Saurin *et al.*, 2011). Mps1 phosphorylates the kinetochore protein Knl1 at Met-Glu-Leu-Thr (MELT) motifs, which recruits Bub1 (Primorac *et al.*, 2013). In turn, Bub1 generates pH2AT120 to recruit Sgo1/Sgo2 and consequently the CPC via the Borealin–Sgo1/Sgo2 interaction. Additionally, Aurora B phosphorylates ataxia telangiectasia mutated (ATM) which enhances the kinase activity of Bub1 (Yang *et al.*, 2011).

Modified View of CPC Targeting

Whether or not the CPC contacts both modified histones in the same complex has not been formally demonstrated. Also, the role of both pH3T3 and pH2AT120 in mediating CPC

Figure 4 Spatial gradient model of CPC-mediated mitotic checkpoint activation. (a) Under low inter-kinetochore tension, the CPC is positioned in close proximity to kinetochores where Aurora B can phosphorylate microtubule-binding kinetochore proteins and reduce their affinity for microtubules. The reduced affinity for microtubules results in dissociation of erroneous kinetochore-microtubule interactions and production of the MCC which activates the mitotic checkpoint. (b) When sister kinetochores come under high tension from bi-orientation, kinetochores are physically separated from Aurora B at centromeres and become dephosphorylated, which stabilizes the kinetochore-microtubule interactions. (c) An Aurora B FRET-sensor placed at centromeres and various locations along the kinetochore reveals a gradient of Aurora B activity along kinetochores. Under low tension, a gradual gradient of Aurora B activity emanates from the inner centromere along the kinetochore axis. However, under high tension the Aurora B phosphorylation gradient is steep.

localization to centromeres may be more complicated. For example, Aurora B localization is unaffected when either Mps1 or Aurora B are inhibited despite large reductions in pH2AT120 (van der Waal *et al.*, 2012). Structure-function analysis of Borealin has also suggested a more complicated view of CPC targeting to the centromere. A small fragment of Borealin from amino acids 1–110 that lacks the reported Sgo-binding region still localizes, although transiently to centromeres (Bekier *et al.*, 2015). Similar transient localization of Borealin to centromeres is observed with a truncated form (amino acids 1–221) containing the central region but lacking the dimerization domain. Replacing the Borealin dimerization domain with FK506-binding protein (FKBP) creates a protein that localizes to centromeres in the absence of a dimeric

rapalogue, but much more strongly when dimerization is induced (Bekier *et al.*, 2015). Interestingly, a small population of Borealin is observed at kinetochores when the bulk of pH3T3 is reduced with a small molecule Haspin inhibitor. Furthermore, monomeric Borealin1-221-FKBP fails to localize to kinetochores after Haspin inhibition, but localization is rescued by adding dimerizer (Bekier *et al.*, 2015). In contrast, Borealin1-110-FKBP fails to localize to kinetochores even when dimerization is induced. Kinetochore localization of full-length Borealin partially overlaps with residual pH2AT120 after Haspin inhibition, although other binding sites cannot be ruled out. Based on these results, a modified model of CPC targeting suggests that two pools of CPC may exist, one at the inner centromere and a second at the kinetochore, the latter of

Figure 5 Two-histone model of CPC localization to centromeres. The CPC engages feedback with Bub1 and Haspin to generate two histone modifications that mediate CPC localization to inner centromeres: Bub1 generates pH2AT120 which recruits Sgo1 and binds the phosphorylated central region of Borealin while Haspin generates pH3T3 which binds the BIR domain of Survivin.

which is most evident in taxol-arrested cells (Bekier *et al.*, 2015). Dimerization of the CPC via Borealin is essential for optimal centromere association. CPC monomers may associate with the inner centromere transiently via a single Survivin/pH3T3 contact, whereas two such contacts allow stable binding in the context of a CPC dimer. Association of the CPC with kinetochores only occurs in a dimer which may allow dual Borealin/pH2AT120 contacts. These results also imply that Survivin binds stronger to its centromere target than the Borealin central region binds its kinetochore target.

CPC during Anaphase, Telophase, and Cytokinesis

The CPC translocates to the spindle midzone at anaphase to help regulate formation and constriction of the cleavage furrow (Carmena, 2008). This transition is under several levels of control. In the budding yeast, transition of the CPC from centromeres to microtubules of the spindle midzone is regulated by Ipl1 (Aurora B)- and Cdc28 (Cdk1)-dependent phosphorylation of the microtubule binding region of Sli15 (INCENP). This phosphorylation, which inhibits microtubule binding is reversed by the phosphatase Cdc14 at the metaphase/anaphase transition. Neither Cdk1 nor Aurora B phosphorylate the microtubule binding site in mammalian INCENP, however Cdk1-dependent phosphorylation of T59 does inhibit association of the CPC with the spindle midzone (Carmena *et al.*, 2012; Hummer and Mayer, 2009). Dephosphorylation of T59 at the metaphase/anaphase transition allows INCENP to interact with the kinesin MKLP2. Both proteins are mutually dependent for midzone targeting, with MKLP2 contributing to microtubule bundling (Hummer and Mayer, 2009). At the spindle midzone, the CPC appears to regulate the cleavage furrow at multiple levels. Aurora B phosphorylates MKLP1 (mitotic kinesin-like protein-1) which is part of the centralspindlin complex composed of two molecules of MKLP1 and two of MgcRacGap (male germ cell Rac-GTPase

activating protein) (Guse *et al.*, 2005). Aurora B-dependent phosphorylation of MKLP1 helps to recruit centralspindlin to the spindle midzone where it is needed to induce furrowing. MgcRacGap, possibly via its Gap activity, inhibits Rac (Canman *et al.*, 2008). Centralspindlin also binds Ect2, a guanine exchange factor that activates Rho in a localized manner to induce actomyosin-dependent contraction in a band that transects the cell equator (marked by the position of the spindle midzone) (Yuce *et al.*, 2005). Additional evidence in *Caenorhabditis elegans* suggests that the CPC has an additional function in inducing constriction of the cleavage furrow, independent of regulating centralspindlin (Lewellyn *et al.*, 2011). The targets for this additional role of the CPC have not been defined; however, depletion of the Septin UNC-59 alleviated the constriction defect observed upon inactivation of CPC but not centralspindlin (Lewellyn *et al.*, 2011). Septins are GTP-binding proteins that form a variety of higher order filamentous structures. Septins are well known as being essential for division in budding yeast, while their contribution to mammalian cell division appears to be cell-type dependent. That CPC might regulate Septin function is an intriguing prospect.

One of the characteristic features of all CPC members is their retention at the midbody during cytokinesis. Experiments in budding yeast first indicated that midbody localization is related to an additional key CPC function in regulating abscission. The NoCut pathway (also known as the abscission checkpoint) blocks abscission in cells that have progressed to cytokinesis with lagging chromosomes in the cleavage plane. In budding yeast, the blockade requires anillin-related proteins Boi1 and Boi2, and can be overridden by inactivating either Ipl1 (Aurora B) or Sli15 (INCENP) (Norden *et al.*, 2006). Furthermore, Boi1 and Boi2 are recruited to the bud neck in cells undergoing abscission delay, but only when Ipl1 is functional. These results suggest a model in which the CPC recruits Boi1 and Boi2 to the cleavage plane when lagging DNA is present. Boi1 and Boi2 then inhibit abscission (Norden *et al.*, 2006).

Although some of the players differ in mammalian cells, it is clear that the CPC also delays abscission in response to DNA in the cleavage furrow. Abscission involves highly coordinated membrane rearrangements and depends on the endosomal sorting complex required for transport (ESCRT) machinery and the VPS4 AAA ATPase. Borealin interacts with an additional protein charged multivesicular body (MVB) protein 4C (CHMP4C), an ESCRT subunit. CHMP4C is required for the abscission delay. Aurora B phosphorylates CHMP4C at serine 210, possibly while it is bound to Borealin (Carlton *et al.*, 2012). S210 phosphorylation by Aurora B is required for CHMP4C to inhibit abscission. To inhibit abscission, phosphorylated CHMP4C collaborates with a new cytokinesis regulator, abscission/NoCut checkpoint regulator (ANCHR) to retain VPS4 at the midbody ring (Thoresen *et al.*, 2014). Only when S210 phosphorylation is reduced is VPS4 released from the CHMP4C-ANCHR complex to catalyze abscission.

Conclusion

Mitosis must occur accurately to ensure that daughter cells contain an intact copy of the genome. This process is

fundamental to the life of all cells, yet we are early in our understanding of how this is all controlled. The CPC contributes in many ways to the accurate segregation of the genome. Starting at its concentration at the centromere where it controls attachment of chromosomes to the spindle, to its monitoring of wayward chromosomes in the cleavage plane that would be fragmented if abscission were allowed to proceed, the CPC is essential for proper movement through mitosis. Given its central role in dividing cells, many attempts are being made to target CPC members in cancer. Inhibitors of Aurora B and Survivin are at various clinical trial stages with some evidence that these treatments may outperform classical chemotherapy regimens (Kantarjian *et al.*, 2013). Future studies that uncover deeper aspect of CPC function may provide new drug targets to investigate.
